# Preface

This book introduces a number of fundamental techniques for computing semantic representations for fragments of natural language and performing inference with the result. Both the underlying theory and their implementation in Prolog are discussed. We believe that the reader who masters these techniques will be in a good position to appreciate (and critically assess) ongoing developments in computational semantics.

Computational semantics is a relatively new subject, and trying to define such a lively area (if indeed it is a single area) seems premature, even counterproductive. However, in this book we take ‘semantics’ to mean ‘formal semantics’ (that is, the business of giving model-theoretic interpretations to fragments of natural language, usually with the help of some intermediate level of logical representation) and ‘computational semantics’ to be the business of using a computer to actually build such representations (*semantic construction*) and reason with the result (*inference*). Thus this book is devoted to introducing techniques for tackling the following two questions:

1. *How can we automate the process of associating semantic representations with expressions of natural language?*
2. *How can we use logical representations of natural language expressions to automate the process of drawing inferences?*

Two comments should immediately be made. First, we’ve presented semantic construction and inference as if they were independent, but of course they’re not. Indeed, how semantic construction and inference can best be interleaved is a deep and important problem. We won’t solve it, but by the end of the book we will have seen some nice examples of semantic construction and inference harnessed together in a single architecture.

Second, our working definition of computational semantics isn’t quite as innocent as it looks. Many semanticists claim that intermediate levels of logical representation are essentially redundant. Whether or not this is true, the move to a computational perspective on formal semantics certainly increases the *practical* importance of the representation level. Logical representations—that is, formulas of a logical language—encapsulate meaning in a clean compact way. They make it possible to use well understood proof systems to

perform inference, and we shall learn how to exploit this possibility. Models may be the heart of semantics, but representations are central to its computational cousin. However, as will become clear in the course of the book, we feel that the computational perspective vividly brings out *theoretical* importance of representations. The success of Discourse Representation Theory, the explosion of interest in underspecification, and the exploration of alternative glue languages such as linear logic to drive the process of semantic construction all bear witness to an important lesson: semanticists ignore representations at their peril. Representations are well-defined mathematical entities that (among other things) can be formed into more abstract entities, explored geometrically, and specified indirectly with the aid of constraints; we'll see examples of all these things in this book. Even if representations are eliminable, they need to be taken seriously.

**Chapter 1. First-Order Logic.** Here we introduce the syntax and semantics of first order logic (the representation language used in the first half of the book), show how formulas and (simple finite) models may be represented in Prolog, build a simple model checker, and discuss the problems that arise when Prolog variables are used to represent first-order variables.

**Chapter 2. Lambda Calculus.** Here we start studying semantic construction. We outline the methodology underlying our work (namely, *compositional-ity*) and motivate our use of Prolog's Definite Clause Grammars. We then write two rather naive programs that build semantic representations for a very small fragment of English. These experiments lead us to the lambda calculus, the tool that drives this book's approach to semantic construction. We implement  $\beta$ -conversion, the computational core of the lambda calculus, in two different ways, and then integrate it into the grammatical architecture that will be used throughout the book.

**Chapter 3. Underspecified Representations.** Here we investigate a fundamental problem for computational semantics: scope ambiguities. These are semantic ambiguities that can arise in syntactically unambiguous expressions, and they pose a problem for compositional approaches to semantic construction. We illustrate the problem, and present four (increasingly more sophisticated) solutions: Montague's use of quantifier raising, Cooper storage, Keller storage, and a more recent underspecification-based method called Hole Semantics. We implement all four approaches.

**Chapter 4. Propositional Inference.** Here we turn to the second major theme of the book: inference. Our approach to inference will be based on first-order theorem proving and model building, and in this chapter we start developing the necessary tools. We introduce a *signed tableaux* system for

propositional calculus, show how to implement it in Prolog, discuss some extensions, and conclude with an informal discussion of a number of theoretical issues.

**Chapter 5. First-Order Inference.** Here we extend our propositional signed tableaux system to full-first order logic—and immediately run into a problem. Naive approaches to first-order tableaux are doomed to hopeless inefficiency. So we rethink the problem. Instead of asking the tableaux system to solve the entire inference problem, we reformulate it so that it generates a collection of constraints on possible solutions. We then feed these constraints to a *unification* component, which (hopefully) will compute a useful solution. As we shall see, this new approach lends itself to computational implementation.

**Chapter 6. Putting It All Together.** In this chapter we combine the techniques we have learned so far. By plugging together our lambda calculus, quantifier storage, model checking, and theorem proving programs we are able (more or less immediately) to define simple question handling and argumentation predicates. Does Vincent give every woman a foot massage? Which robber loves Honey Bunny? Find out in this week’s exciting episode . . .

Each chapter concludes with two sections: *Software Summary* lists the programs developed in the chapter, and *Notes* lists references the reader may find helpful, and discusses more advanced topics.

We have tried to make this book self-contained, and believe that readers with relatively modest backgrounds in linguistics and logic should be able to follow the theoretical discussion. But the fact remains that this is a book in *computational* semantics, and getting the most out of it requires a working knowledge of Prolog. We have included an appendix which outlines the main ideas of Prolog, and we hope that this will be useful—but, bluntly, the reader who has never thought about computational problems from the declarative perspective typical of logic or constraint-based programming will find parts of it tough going. We develop many theoretical ideas by thinking problems through from a declarative perspective. For example, our account of the lambda calculus in Chapter 2 makes no appeal to types, function valued functions, or higher-order logic—rather, lambda calculus is presented as a beautiful piece of data-abstraction that emerges naturally from a declarative analysis of semantic construction. Computational ideas are not an optional extra in computational semantics; they are the heart of the enterprise.

This book developed out of material for a course on Computational Semantics we regularly offer at the Department of Computational Linguistics, University of the Saarland. We also taught a preliminary version (essentially the material that now makes up Part I) as an introductory course at ESSLLI’97, the *European Summer School in Logic, Language and Information* held at Aix-en-Provence, France in August 1997. When designing these

courses, we found no single source which contained all the material we wanted to present. At that time, the only notes solely devoted to computational semantics we knew of were Cooper et al. 1993. These notes, which we recommend to our readers, were developed at the University of Edinburgh, and are probably the first systematic introduction to modern computational semantics. Like the present book they are Prolog based, and cover some of the same ground using interestingly different tools and techniques. However we wanted to teach the subject in a way that emphasized such ideas as inference, underspecification, and architectural issues. This led us to a first version of the book, which was heavily influenced by Pereira and Shieber 1987 for semantic construction, and Fitting 1996 and Smullyan 1995 for tableaux systems. Since then, the project has taken on a life of its own, and grown in a variety of (often unexpected) directions. Both the code and the text has been extensively rewritten and we are now (we hope!) in the final stretch of producing the kind of introduction to computational semantics that we wanted all along.

## Acknowledgments

We would like to thank Manfred Pinkal and all our colleagues at the Department of Computational Linguistics, University of Saarland, Saarbrücken, Germany. Thanks to Manfred, the department has become an extremely stimulating place for working on computational semantics; it was the ideal place to write this book.

Johan Bos would like to thank his colleagues in the *Verbmobil* Project (grant 01 IV 701 R4 and 01 IV 701 N3) at IMS-Stuttgart, TU-Berlin, CSLI Stanford, the DFKI, and the Department of Computational Linguistics at Saarbrücken, and those in the Trindi Project (Task Oriented Instructional Dialogue; LE4-8314) at the University of Gothenburg, SRI Cambridge, University of Edinburgh, and Xerox Grenoble.

Conversations with Paul Dekker, Andreas Franke, Martin Kay, Hans Kamp, Michael Kohlhase, Karsten Konrad, Christof Monz, Reinhard Muskens, Maarten de Rijke, and Henk Zeevat were helpful in clarifying our goals. We're grateful to David Beaver, Judith Baur, Björn Gambäck, Ewan Klein, Emiel Krahmer, Rob van der Sandt, and Frank Schilder for their comments on an early draft of this book. We're also very grateful to all our students, who have provided us with invaluable feedback. In particular we would like to thank Aljoscha Burchardt, Gerd Fliedner, Malte Gabsdil, Kristina Striegnitz, Stefan Thater, and Stephan Walter. Patrick Blackburn would like to thank Aravind Joshi and the staff of Institute for Research in Cognitive Science at the University of Pennsylvania for their hospitality while the Montreal version was being prepared.

Finally, we are deeply grateful to Robin Cooper, who taught a course based on the previous draft of this book, and provided us with extremely detailed feedback on what worked and what didn't. His comments have greatly improved the book.

September 1999.*

# Chapter 1

## First-Order Logic

First-order logic is the formalism used in the first half of this book to represent the meaning of natural language sentences. In this chapter we introduce first-order logic, write some simple Prolog programs that work with it, and discuss the role of first-order logic in natural language semantics.

Here's what we'll do. First, we'll discuss the syntax and semantics of first-order logic. Next, we'll write a simple first-order model checker (or semantic evaluator) in Prolog. The model checker takes a first-order formula and a (special kind of) first-order model as input and checks whether the formula is satisfied in the model. As we shall see, such a model checker is extremely simple to implement if we use Prolog variables to simulate first-order variables, but this strategy leads to problems if carried out naively; we discuss these problems and show how to deal with them. We conclude with a discussion of the relevance of first-order logic to natural language semantics.

### 1.1 First-Order Logic

In this section we review the syntax and semantics of first-order logic. We discuss *vocabularies*, *first-order models* and *first-order languages*, tie them together via the crucial *satisfaction* definition, define the key logical concepts of *validity* and *logical consequence*, and conclude with a discussion of *function symbols* and *equality*.

#### Vocabularies

Our ultimate goal is to define how first-order formulas (that is, certain kinds of descriptions) are evaluated in first-order models (that is, certain kinds of situations). Simplifying somewhat, the purpose of the evaluation process is to tell us whether a description is true or false in a situation.

We shall shortly do this—but we need to exercise a little care. Intuitively, it doesn't make much sense to ask whether or not an arbitrary description is true in an arbitrary situation. Some descriptions and situations simply don't belong together. For example, if we are given a formula (that is, a description) from a first-order language intended for talking about the various relationships and properties (such as *loving*, *being a robber*, and *being a customer*) that hold between Mia, Honey Bunny, Vincent, and Pumpkin, and we are given a model (that is, a situation) which records information about something completely different (for example, which household cleaning products are best at getting rid of particularly nasty stains) then it doesn't really make much sense to evaluate this particular formula in that particular model. *Vocabularies* allow us to avoid such problems: they tell us which first-order languages and models belong together.

Here is our first vocabulary:

$$\{ \begin{array}{l} (\text{LOVE}, 2), \\ (\text{CUSTOMER}, 1), \\ (\text{ROBBER}, 1), \\ (\text{MIA}, 0), \\ (\text{VINCENT}, 0), \\ (\text{HONEY-BUNNY}, 0), \\ (\text{PUMPKIN}, 0) \end{array} \}$$

Intuitively, this vocabulary is telling us two important things: the topic of conversation, and the language the conversation is going to be conducted in. Let's spell out this a little.

First, the vocabulary tells us *what* we're going to be talking about. In the present case, we're going to be talking about *loving* (the 2 indicates that loving is taken to be a two place relation) and the properties (or 1-place relations) of *being a customer* and *being a robber*. In addition to these relations we're going to be talking about four special entities named *Mia*, *Honey Bunny*, *Vincent*, and *Pumpkin* (the 0s indicate that these symbols are constants, or names).

Second, the vocabulary also tells us *how* we can talk about these things. In the above case it tells us that we will be using a symbol LOVE of arity 2 (that is, a 2-place symbol) for talking about loving, two symbols of arity 1 (CUSTOMER and ROBBER) for talking about customers and robbers, and four constant symbols (or names), namely MIA, VINCENT, HONEY-BUNNY, and PUMPKIN for naming certain entities of special interest.

In short, a vocabulary gives us all the information needed to define the class of models of interest (that is, the kinds of situations we want to describe) and the relevant first-order language (that is, the kinds of descriptions we can use). So let's now look at what first-order models and languages actually are.

## First-Order Models

Suppose we've fixed some vocabulary. What should a first-order *model* for this vocabulary be?

Actually, our previous discussion has pretty much given the answer. Intuitively a model is a situation. That is, it is a *semantic* entity: it contains the kinds of things we want to talk about. Thus a model for a given vocabulary gives us two pieces of information. First, it tells us which collection of entities we are talking about; this collection is usually called the *domain*. Second, for each symbol in the vocabulary, it gives us an appropriate semantic entity, built from the items in  $D$ . This task is carried out by a function  $F$  which specifies, for each symbol in the vocabulary, an appropriate semantic value; we call such functions *interpretation functions*. Thus, in set theoretic terms, a model  $\mathbf{M}$  is an ordered pair  $(D, F)$  consisting of a domain  $D$  and an interpretation function  $F$  specifying semantic values in  $D$ .

What are appropriate semantic values? There's no mystery here. As constants are names, each constant should be interpreted as an element of  $D$ . (That is, for each constant symbol  $c$  in the vocabulary,  $F(c) \in D$ .) As  $n$ -place relation symbols are intended to denote  $n$ -place relations, each  $n$ -place relation symbol  $R$  should be interpreted as an  $n$ -place relation on  $D$ . (That is,  $F(R)$  should be a set of  $n$ -tuples of elements of  $D$ .)

Let's consider an example. We shall define a simple model for the vocabulary given above. Let  $D$  be  $\{d_1, d_2, d_3, d_4\}$ . That is, this four element set is the domain of our little model.

Next, we must specify an interpretation function  $F$ . Here's one possibility:

$$\begin{aligned} F(\text{MIA}) &= d_1 \\ F(\text{HONEY-BUNNY}) &= d_2 \\ F(\text{VINCENT}) &= d_3 \\ F(\text{PUMPKIN}) &= d_4 \\ F(\text{CUSTOMER}) &= \{d_1, d_3\} \\ F(\text{ROBBER}) &= \{d_2, d_4\} \\ F(\text{LOVE}) &= \{(d_4, d_2), (d_3, d_1)\} \end{aligned}$$

Note that every symbol in the vocabulary does indeed correspond to an appropriate semantic entity. The four names pick out individuals, the two arity 1 symbols pick out subsets of  $D$  (that is, properties, or 1-place relations on  $D$ ) and the arity 2 symbol picks out a 2-place relation on  $D$ . Intuitively, in this model  $d_1$  is called Mia,  $d_2$  is called Honey Bunny,  $d_3$  is called Vincent and  $d_4$  is called Pumpkin. Both Honey Bunny and Pumpkin are robbers, while both Vincent and Mia are customers. Pumpkin loves Honey Bunny and Vincent loves Mia. Sadly, Honey Bunny does not love Pumpkin, Mia does not love Vincent, and nobody loves themselves.

Here's a second model for the same vocabulary. We'll use the same domain (that is,

$D = \{d_1, d_2, d_3, d_4\}$ ) but change the interpretation function. To emphasize that the interpretation function has changed, we'll use a different symbol (namely  $F_2$ ) for it.

$$\begin{aligned}
 F_2(\text{MIA}) &= d_2 \\
 F_2(\text{HONEY-BUNNY}) &= d_1 \\
 F_2(\text{VINCENT}) &= d_4 \\
 F_2(\text{PUMPKIN}) &= d_3 \\
 F_2(\text{CUSTOMER}) &= \{d_1, d_2, d_4\} \\
 F_2(\text{ROBBER}) &= \{d_3\} \\
 F_2(\text{LOVE}) &= \{(d_3, d_4)\}
 \end{aligned}$$

In this model, three of the individuals are customers, only one is a robber, and Pumpkin loves Vincent.

One point is worth emphasizing. Both models just defined are rather special, for they have the following property: *every entity in  $D$  is named by exactly one constant*. We shall call any model with this property an *exact* model. Now, exact models are particularly easy to work with, but it is important to realize that not all models are exact. For example, suppose we add two more entities to the domain of the first model; that is, we create a new domain  $D' = D \cup \{d_5, d_6\}$  say. Suppose that we then define a new interpretation function  $F'$  on  $D'$  as follows:

$$\begin{aligned}
 F'(\text{MIA}) &= d_2 \\
 F'(\text{HONEY-BUNNY}) &= d_1 \\
 F'(\text{VINCENT}) &= d_4 \\
 F'(\text{PUMPKIN}) &= d_3 \\
 F'(\text{CUSTOMER}) &= \{d_1, d_2, d_4, d_5\} \\
 F'(\text{ROBBER}) &= \{d_3, d_6\} \\
 F'(\text{LOVE}) &= \{(d_3, d_4), (d_6, d_5)\}
 \end{aligned}$$

This new model is like our very first model, except that it has two extra entities. Neither of these new entities has a name, but one of them is a customer, one of them is a robber, and the unnamed robber loves the unnamed customer. This *is* a perfectly good first-order model; there is no requirement that every entity in the model must have a name (we only bother to name entities of special interest). Similarly, there is no requirement that each entity in a model must be named by at most one constant. For example, if we wanted to we could give some entity both the name Vincent and Honey Bunny (perhaps one of these names is a nickname).

## First-Order Languages

Given some vocabulary, we build *the first-order language over that vocabulary* out of the following ingredients:

1. All the symbols in the vocabulary. We call these symbols the *non-logical* symbols of the language.
2. A countably infinite collection of variables  $x, y, z, w, \dots$ , and so on.
3. The Boolean connectives  $\neg$  (negation),  $\rightarrow$  (implication),  $\vee$  (disjunction), and  $\wedge$  (conjunction).
4. The quantifiers  $\forall$  (the universal quantifier) and  $\exists$  (the existential quantifier).
5. The round brackets  $)$  and  $($  and the comma. (These are essentially punctuation marks; they are used to group symbols.)

Items 2–5 are common to all first-order languages: the only thing that distinguishes one first-order language from another is the choice of non-logical symbols (that is, the choice of vocabulary).

So, suppose we've chosen some vocabulary. How do we mix these ingredients together? That is, what is the *syntax* of first-order languages? First of all, we define a first-order *term*  $\tau$  to be any constant or any variable. Roughly speaking, terms are the noun phrases of first-order languages: constants can be thought of as first-order analogs of proper names, and variables as first-order analogs of pronouns.

We can then combine our 'noun phrases' with our 'predicates' (that is, the various relation symbols in the vocabulary) to form *atomic formulas*:

If  $R$  is a relation symbol of arity  $n$ , and  $\tau_1, \dots, \tau_n$  are terms, then  $R(\tau_1, \dots, \tau_n)$  is an atomic (or basic) formula.

Intuitively, an atomic formula is the first-order counterpart of a natural language sentence consisting of a single clause (that is, a simple sentence). The intended meaning of  $R(\tau_1, \dots, \tau_n)$  is that the entities named by the terms  $\tau_1, \dots, \tau_n$  stand in the relation named by the symbol  $R$ . For example

LOVE(PUMPKIN, HONEY-BUNNY)

means that the entity named PUMPKIN stands in the relation denoted by LOVE to the entity named HONEY-BUNNY—or more simply, that Pumpkin loves Honey Bunny.

Now that we know how to build atomic formulas, we can define more complex descriptions. The following inductive definition tells us exactly which *well formed formulas* (or *wffs*, or simply *formulas*) we can form.

1. All atomic formulas are wffs.

2. If  $\phi$  and  $\psi$  are wffs then so are  $\neg\phi$ ,  $(\phi \rightarrow \psi)$ ,  $(\phi \vee \psi)$ , and  $(\phi \wedge \psi)$ .
3. If  $\phi$  is a wff, and  $x$  is a variable, then both  $\exists x\phi$  and  $\forall x\phi$  are wffs. (We call  $\phi$  the *matrix* of such wffs.)
4. Nothing else is a wff.

Roughly speaking, formulas built using  $\neg$ ,  $\rightarrow$ ,  $\vee$  and  $\wedge$  correspond to natural language expressions of the form **it is not the case that ...**, **if ... then ...**, **... or ...**, and **... and ...**, respectively. (We discuss the strengths and weaknesses of these correspondences at the end of the chapter.) First-order formulas of the form  $\exists x\phi$  and  $\forall x\phi$  correspond to natural language expressions of the form **some... or all ...**.

In what follows, we occasionally talk of *subformulas*. The subformulas of a formula  $\phi$  are  $\phi$  itself and all the formulas used to build  $\phi$ . For example, the subformulas of

$$\neg\forall y \text{ PERSON}(y)$$

are  $\text{PERSON}(y)$ ,  $\forall y \text{ PERSON}(y)$ , and  $\neg\forall y \text{ PERSON}(y)$ . We leave it to the interested reader to give an inductive definition of subformulahood, and turn to a more important topic: the distinction between *free* and *bound* variables.

Consider the following formula:

$$\neg (\text{CUSTOMER}(x) \vee \forall x(\text{ROBBER}(x) \wedge \forall y \text{ PERSON}(y)))$$

The first occurrence of  $x$  is *free*. The second and third occurrences of  $x$  are *bound*; they are bound by the first occurrence of the quantifier  $\forall$ . The first and second occurrences of the variable  $y$  are also bound; they are bound by the second occurrence of the quantifier  $\forall$ . Here's the full definition:

1. Any occurrence of any variable is free in any atomic formula.
2. No occurrence of any variable is bound in any atomic formula.
3. If an occurrence of any variable is free in  $\phi$  or in  $\psi$ , then that same occurrence is free in  $\neg\phi$ ,  $(\phi \rightarrow \psi)$ ,  $(\phi \vee \psi)$ , and  $(\phi \wedge \psi)$ .
4. If an occurrence of any variable is bound in  $\phi$  or in  $\psi$ , then that same occurrence is bound in  $\neg\phi$ ,  $(\phi \rightarrow \psi)$ ,  $(\phi \vee \psi)$ ,  $(\phi \wedge \psi)$ . Moreover, that same occurrence is bound in  $\forall y\phi$  and  $\exists y\phi$ , for any choice of variable  $y$ .
5. In any formula of the form  $\forall y\phi$  or  $\exists y\phi$  (here  $y$  can be any variable at all) the occurrence of  $y$  that immediately follows the initial quantifier symbol is bound.

6. If an occurrence of a variable  $x$  is free in  $\phi$ , then that same occurrence is free in  $\forall y\phi$  and  $\exists y\phi$ , for any variable  $y$  distinct from  $x$ . On the other hand, all occurrences of  $x$  that are free in  $\phi$ , are bound in  $\forall x\phi$  and in  $\exists x\phi$ .

If a formula contains no occurrences of free variables then we call it a *sentence*.

Although they are both called variables, free and bound variables are really very different. (In fact, some formulations of first-order logic use two distinct kinds of symbol for what we have lumped together under the heading ‘variable’.) Here’s an analogy. Try thinking of a free variable as something like the pronoun *she* in

She even has a stud in her tongue.

Uttered in isolation, this would be somewhat puzzling, as we don’t know who *she* refers to. But of course, such an utterance would be made in an appropriate *context*. This context might be either non-linguistic (for example, the speaker might be pointing to a heavily tattooed biker, in which case we would say that *she* was being used *deictically* or *demonstratively*) or linguistic (perhaps the speaker’s previous sentence was *Honey Bunny is heavily into body piercing*, in which case the name *Honey Bunny* supplies a suitable anchor for an *anaphoric* interpretation of *she*).

What’s the point of the analogy? Just as the pronoun *she* required something else (namely, contextual information) to supply a suitable referent, so will formulas containing free variables. Simply supplying a model won’t be enough; we need additional information on how to link the free variables to the entities in the model.

Sentences, on the other hand, are relatively self-contained. For example, consider the sentence  $\forall x \text{ ROBBER}(x)$ . This is a claim that *every* individual is a robber. Roughly speaking, the bound variable  $x$  in  $\text{ROBBER}(x)$  acts as a sort of placeholder. In fact, the use of  $x$  is completely arbitrary; the sentence  $\forall y \text{ ROBBER}(y)$  means exactly the same thing. Both sentences are simply a way of stating that no matter what entity we take the second occurrence of  $x$  (or  $y$ ) as standing for, that entity will be a robber. In any model of appropriate vocabulary this sentence (and in fact *any* sentence over that vocabulary) will either be true or false.

Our discussion of the interpretation of first-order languages in first-order models will make these distinctions precise (indeed, most of the real work involved in interpreting first-order logic centers on the correct handling of free and bound variables). But before turning to semantic issues, one final remark. In what follows, we won’t always keep to the official first-order syntax defined above. In particular, we’ll generally try and use as few brackets as possible, as this tends to improve readability. For example, we would rarely write

( $\text{CUSTOMER}(\text{VINCENT}) \wedge \text{ROBBER}(\text{PUMPKIN})$ )

which is the official syntax. Instead, we would (almost invariably) drop the outermost brackets and write

$$\text{CUSTOMER}(\text{VINCENT}) \wedge \text{ROBBER}(\text{PUMPKIN})$$

To help further reduce the bracket count, we assume the following precedence conventions for the Boolean connectives:  $\neg$  binds more tightly than  $\vee$  and  $\wedge$ , both of which in turn bind more tightly than  $\rightarrow$ . What this means, for example, is that the formula

$$\forall x (\neg \text{CUSTOMER}(x) \wedge \text{ROBBER}(x) \rightarrow \text{ROBBER}(x))$$

is shorthand for the following:

$$\forall x ((\neg \text{CUSTOMER}(x) \wedge \text{ROBBER}(x)) \rightarrow \text{ROBBER}(x))$$

In addition, we sometimes use the square brackets  $]$  and  $[$  as well as the official round brackets, as this can make the intended grouping of symbols easier to grasp visually.

## The Satisfaction Definition

Given a model of appropriate vocabulary, a sentence such as  $\forall x \text{ROBBER}(x)$  is either true or false in that model. To put it more formally, there is a relation called *truth* which holds, or does not hold, between sentences and models of the same vocabulary. Now it is often obvious how to check whether a given sentence is true in a given model (for example, to check the truth of  $\forall x \text{ROBBER}(x)$  we simply need to check that every individual in the model is a robber). What is not so clear is how to give a precise definition of this relation for arbitrary sentences.

Note that we cannot give a *direct* inductive definition of truth, for the matrix of a quantified sentence typically won't be a sentence. For example,  $\forall x \text{ROBBER}(x)$  is a sentence, but its matrix  $\text{ROBBER}(x)$  is not. Thus an inductive truth definition defined solely in terms of sentences couldn't explain why  $\forall x \text{ROBBER}(x)$  was true in a model, for there are no sentential subformulas for such a definition to bite on.

Instead we proceed indirectly. We define a three place relation—called *satisfaction*—which holds between a formula, a model, and an *assignment of values to variables*. Given a model  $\mathbf{M} = (D, F)$ , an assignment of values to variables in  $\mathbf{M}$  (or more simply, an *assignment* in  $\mathbf{M}$ ) is a function  $g$  from the set of variables to  $D$ . Assignments are a technical device which tell us what the free variables stand for. By making use of assignment functions, we can inductively interpret *arbitrary* formulas in a natural way, and this will make it possible to define the concept of truth for *sentences*.

But before going further, one point is worth stressing: the reader should *not* view assignment functions simply as a technical fix designed to get round the problem of defining truth. Moreover, the reader should *not* think of satisfaction as being a poor relation of truth. If anything, satisfaction, not truth, is the fundamental notion, at least as far as natural language is concerned. Why is this?

The key to the answer is the word *context*. As we said earlier, free variables can be thought of as analogs of pronouns, whose values need to be supplied by context. An assignment of values to variables can be thought of as a (highly idealized) mathematical model of context; it rolls up all the contextual information into one easy to handle unit, specifying a denotation for every free variable. Thus if we want to use first-order logic to model natural language semantics, it is sensible to think in terms of three components: first-order formulas (descriptions), first-order models (situations) and variable assignments (contexts). The idea of assignment-functions-as-contexts is important in contemporary formal semantics; it has a long history and has been explored in a number of interesting directions. We shall periodically return to it in the course of the book, particularly when we discuss Discourse Representation Theory in Part II.

But let's return to the satisfaction definition. Suppose we've fixed our vocabulary. (That is, from now on, when we talk of a model  $\mathbf{M}$ , we mean a model of this vocabulary, and whenever we talk of formulas, we mean the formulas built from the symbols in that vocabulary.) We now give two further technical definitions which will enable us to state the satisfaction definition concisely.

First, let  $\mathbf{M} = (D, F)$  be a model, let  $g$  be an assignment of values to variables in  $\mathbf{M}$ , and let  $\tau$  be a term. Then by the *interpretation* of  $\tau$  with respect to  $\mathbf{M}$  and  $g$  is meant  $F(\tau)$  if  $\tau$  is a constant, and  $g(\tau)$  if  $\tau$  is a variable. We denote the interpretation of  $\tau$  by  $I_F^g(\tau)$ .

The second idea we need is that of a *variant* of an assignment of values to variables. So, let  $g$  be an assignment of values to variables in some model, and let  $x$  be a variable. If  $g'$  is an assignment of values to variables in the same model, and for all variables  $y$  such that  $y \neq x$ ,  $g'(y) = g(y)$  then we say that  $g'$  is an *x-variant* of  $g$ . Variant assignments are the technical tool that allows us to try out new values for a given variable (say  $x$ ) while keeping the values assigned to all other variables the same.

We are now ready for the satisfaction definition. Let  $\phi$  be a formula, let  $\mathbf{M} = (D, F)$  be a model, and let  $g$  be an assignment of values to variables in  $\mathbf{M}$ . Then the relation  $\mathbf{M}, g \models \phi$  ( $\phi$  is satisfied in  $\mathbf{M}$  with respect to the assignment of values to variables  $g$ ) is defined inductively as follows:

$\mathbf{M}, g \models R(\tau_1, \dots, \tau_n)$	<i>iff</i>	$(I_F^g(\tau_1), \dots, I_F^g(\tau_n)) \in F(R)$
$\mathbf{M}, g \models \neg\phi$	<i>iff</i>	not $\mathbf{M}, g \models \phi$
$\mathbf{M}, g \models \phi \wedge \psi$	<i>iff</i>	$\mathbf{M}, g \models \phi$ and $\mathbf{M}, g \models \psi$
$\mathbf{M}, g \models \phi \vee \psi$	<i>iff</i>	$\mathbf{M}, g \models \phi$ or $\mathbf{M}, g \models \psi$
$\mathbf{M}, g \models \phi \rightarrow \psi$	<i>iff</i>	not $\mathbf{M}, g \models \phi$ or $\mathbf{M}, g \models \psi$
$\mathbf{M}, g \models \exists x\phi$	<i>iff</i>	$\mathbf{M}, g' \models \phi$ , for some x-variant $g'$ of $g$
$\mathbf{M}, g \models \forall x\phi$	<i>iff</i>	$\mathbf{M}, g' \models \phi$ , for all x-variants $g'$ of $g$

(Here ‘iff’ is shorthand for ‘if and only if’.) Note the crucial—and indeed, intuitive—role played by the x-variants in the clauses for the quantifiers. For example, what the clause for the existential quantifier boils down to is this:  $\exists x\phi$  is satisfied in a given model, with respect to an assignment  $g$ , if and only if there is some x-variant  $g'$  of  $g$  that satisfies  $\phi$  in the model. That is, we have to try to find *some* value for  $x$  that satisfies  $\phi$  in the model, while keeping the assignments to all other variables the same.

We can now define what it means for a *sentence* to be true in a model:

A sentence  $\phi$  is true in a model  $\mathbf{M}$  if and only if for *any* assignment  $g$  of values to variables in  $\mathbf{M}$ , we have that  $\mathbf{M}, g \models \phi$ . If  $\phi$  is true in  $\mathbf{M}$  we write  $\mathbf{M} \models \phi$

This is an elegant definition of truth that beautifully mirrors the special, self-contained nature of sentences. It hinges on the following observation: *it simply doesn't matter which variable assignment we use to compute the satisfaction of sentences*. Sentences contain no free variables, so the only free variables we will encounter when evaluating one are those produced when evaluating its quantified subformulas (if it has any). But the satisfaction definition tells us what to do with such free variables: simply try out variants of the current assignment and see whether they satisfy the matrix or not. In short, start with whatever assignment you like; the result will be the same. It is reasonably straightforward to make this informal argument precise, and the reader is asked to do so in Exercise 1.1.1.

Still, for all the elegance of the truth definition, satisfaction is the fundamental concept. Not only is satisfaction the technical engine powering the definition of truth, but from the perspective of natural language semantics it is conceptually prior. By making *explicit* the role of variable assignments, it holds up an (admittedly imperfect) mirror to the process of evaluating descriptions in situations while making use of contextual information.

**Exercise 1.1.1** We claimed that when evaluating *sentences*, it doesn't matter which variable assignment we start with. Formally, we are claiming that given any *sentence*  $\phi$  and any model  $\mathbf{M}$  (of the same vocabulary), and any variable assignments  $g$  and  $g'$  in  $\mathbf{M}$ , then  $\mathbf{M}, g \models \phi$  iff  $\mathbf{M}, g' \models \phi$ . We want the reader to do two things. First, show that the claim is *false* if  $\phi$  is not a sentence but a formula containing free variables. Second, show that the claim is *true* if  $\phi$  is a *sentence*.

**Exercise 1.1.2** This exercise shows that free variables and constants are very similar. In particular, if a free variable  $x$  and a constant  $c$  denote the same individual, we can replace the free variable by the constant without affecting satisfiability. Formally, let  $\mathbf{M} = (D, F)$  be a model, let  $g$  be an assignment in  $\mathbf{M}$ , and suppose that  $F(c) = g(x)$ . Let  $\phi$  be any formula, and let  $\phi[c/x]$  denote the formula obtained by replacing all free occurrences of  $x$  in  $\phi$  by  $c$ . Then  $\mathbf{M}, g \models \phi$  iff  $\mathbf{M}, g' \models \phi[c/x]$ , where  $g'$  is any  $x$ -variant of  $g$ . It follows that when working with *exact* models, every formula is equivalent to a sentence. Explain why.

## Validities and Valid Arguments

In this book we are going to make heavy use of *logical inference*, and by making use of the semantic concepts just introduced we can explain what we mean by this. We do so in two steps. First we say what *valid formulas* (or more simply, *validities*) are, and then we define *valid arguments* (or *valid inferences*).

A valid formula is a formula that is satisfied in *all* models (of the appropriate vocabulary) given *any* variable assignment. That is, if  $\phi$  is a valid formula, it is impossible to find a situation and a context in which  $\phi$  is not satisfied. We indicate that a formula  $\phi$  is valid by writing  $\models \phi$ .

For example,

$$\models \text{ROBBER}(x) \vee \neg \text{ROBBER}(x).$$

In any model, given any variable assignment, one (and indeed, only one) of the two disjuncts must be true, and hence the whole formula will be satisfied too.

Note that for *sentences* the definition of validity can be rephrased as follows: a valid sentence is a sentence that is true in all models (of the appropriate vocabulary). That is, it is impossible to falsify a valid sentence. For example,

$$\models \forall x(\text{ROBBER}(x) \rightarrow \text{CUSTOMER}(x)) \wedge \text{ROBBER}(\text{MIA}) \rightarrow \text{CUSTOMER}(\text{MIA}).$$

**Exercise 1.1.3** This exercise shows that the validity of arbitrary formulas is equivalent to the validity of certain sentences. As a first step, the reader should show that if  $\phi$  is a formula containing  $x$  as a free variable, then  $\phi$  is valid iff  $\forall x\phi$  is valid. It follows that the validity of formulas is reducible to the validity of sentences. Explain why. [Hint: we've just found a way of reducing number of free variables by one while maintaining validity. Iterate this process.]

Now, validities are clearly in some sense *logical*; they are descriptions which carry a cast-iron guarantee of satisfiability. But logic has traditionally appealed to the more dynamic notion of *valid arguments*, a movement, or inference, from premises to conclusions.

Suppose  $\phi_1, \dots, \phi_n$ , and  $\psi$  are a finite collection of first-order formulas. Then we say that the argument with *premises*  $\phi_1, \dots, \phi_n$  and *conclusion*  $\psi$  is a *valid argument* if and only if whenever all the premises are satisfied in some model, using some variable assignment, then the conclusion is satisfied in the same model using the same variable assignment. The notation

$$\phi_1, \dots, \phi_n \models \psi$$

means that the argument with premises  $\phi_1, \dots, \phi_n$  and conclusion  $\psi$  is valid. There is a wide range of terminology for talking about valid arguments. For example, we sometimes say that  $\psi$  is a *valid inference* from the premises  $\phi_1, \dots, \phi_n$ , or that  $\psi$  is a *logical consequence* of  $\phi_1, \dots, \phi_n$ .

Note that if the premises and conclusion are all *sentences* the definition of valid argument can be rephrased as follows: an argument is valid if whenever the premises are true in some model, the conclusion is too. Or more simply: the truth of the premises guarantees the truth of the conclusion.

Here's an example. The argument with premises  $\forall x(\text{ROBBER}(x) \rightarrow \text{CUSTOMER}(x))$  and  $\text{ROBBER}(\text{MIA})$  and the conclusion  $\text{CUSTOMER}(\text{MIA})$  is valid. That is,

$$\forall x(\text{ROBBER}(x) \rightarrow \text{CUSTOMER}(x)), \text{ROBBER}(\text{MIA}) \models \text{CUSTOMER}(\text{MIA}).$$

As the reader may suspect, there is a connection between the validity of this argument and the fact that

$$\models \forall x(\text{ROBBER}(x) \rightarrow \text{CUSTOMER}(x)) \wedge \text{ROBBER}(\text{MIA}) \rightarrow \text{CUSTOMER}(\text{MIA}).$$

This example suggests that with the help of the Boolean connectives  $\wedge$  and  $\rightarrow$  we can convert valid arguments into validities. The reader is asked to explore this in Exercise 1.1.5 below.

Validity and valid arguments are the fundamental logical concepts, and they underly the treatment of inference in this book. Both concepts are semantically defined (that is, they are defined in terms of models and variable assignments) but in Chapters 4 and 5 we will find a syntactic way of thinking about them that lends itself to computational implementation (that is, we will develop various *proof systems*). Moreover, as we shall learn in Part II, these concepts provide a useful basis for discussing inference in Discourse Representation Theory.

This concludes our review of the syntax and semantics of first-order logic. We finish with a global remark. As the reader has doubtless observed, most of the ideas we have discussed are fairly straightforward—with the notable exception of variable handling. This required a certain amount of care, and the introduction of concepts such as assignments and variant assignments. Unsurprisingly, if we want to work with first-order logic in Prolog, the key issue that faces us is how to cope with variables. Indeed, the theme of how best to handle variables recurs in various guises throughout the book.

**Exercise 1.1.4** We say that two sentences  $\phi$  and  $\psi$  are *logically equivalent* if and only if  $\phi \models \psi$  and  $\psi \models \phi$ . Show that  $\forall x\phi$  and  $\neg\exists x\neg\phi$  are logically equivalent.

**Exercise 1.1.5** The *Deduction Theorem* for first-order logic says that  $\phi_1, \dots, \phi_n \models \psi$  if and only if  $\models (\phi_1 \wedge \dots \wedge \phi_n) \rightarrow \psi$ . (That is, there is an intimate link between validities and valid arguments.) Prove the Deduction Theorem.

**Exercise 1.1.6** Show that the validity of arguments whose premises or conclusions contain free variables, is reducible to the validity of arguments whose premises and conclusions are sentences. [Hint: think about Exercise 1.1.3.]

## Function Symbols and Equality

We now discuss two important extensions of first-order logic; namely first-order logic with function symbols, and first-order logic with equality. Function symbols play an important role when we discuss first-order inference in Chapter 5. Equality plays an important role in our discussion of Discourse Representation Theory in Part II.

Suppose we want to talk about Butch, Butch's father, Butch's grandfather, Butch's great grandfather, and so on. Now, if we know the names of all these people this is easy to do—but what if we don't? A natural solution is to add a 1-place function symbol FATHER to the language. Then if BUTCH is the constant that names Butch, FATHER(BUTCH) is a term that picks out Butch's father, FATHER(FATHER(BUTCH)) picks out Butch's grandfather, and so on. That is, function symbols are a syntactic device that let us form recursively structured terms, thus letting us express many concepts in a natural way.

Let's make this precise. First, we shall suppose that it is the task of the vocabulary to tell us which function symbols we have at our disposal, and what the arity of each of these symbols is. Second, given this information, we say (as before) that a model  $\mathbf{M}$  is a pair  $(D, F)$  where  $F$  interprets the constants and relation symbols as described earlier, and, in addition,  $F$  assigns to each function symbol  $f$  an appropriate semantic entity. What's an appropriate interpretation for an  $n$ -place function symbol? Simply a function that takes  $n$ -tuples of elements of  $D$  as input, and returns an element of  $D$  as output. Third, we need to say what terms we can form using these new symbols. Here's the definition we require:

1. All constants and variables are terms.
2. If  $f$  is a function symbol of arity  $n$ , and  $\tau_1, \dots, \tau_n$  are terms, then  $f(\tau_1, \dots, \tau_n)$  is also a term.
3. Nothing else is a term.

A term is said to be *closed* if and only if it contains no variables.

Only one task remains: interpreting these new terms. In fact we need simply extend our earlier definition of  $I_F^g$  in the obvious way. Given a model  $\mathbf{M}$  and an assignment  $g$  in  $\mathbf{M}$ , we define (as before)  $I_F^g(\tau)$  to be  $F(\tau)$  if  $\tau$  is a constant, and  $g(\tau)$  if  $\tau$  is a variable. On the other hand, if  $\tau$  is a term of the form  $f(\tau_1, \dots, \tau_n)$ , then we define  $I_F^g(\tau)$  to be  $F(f)(I_F^g(\tau_1), \dots, I_F^g(\tau_n))$ . (That is, we apply the  $n$ -place function  $F(f)$ —the function interpreting  $f$ —to the interpretation of the  $n$  argument terms.)

Function symbols are certainly a natural extension to first-order languages, as the fatherhood example should suggest. However, they are also important for more technical purposes. In particular, they play a key role in Chapter 5, where they will help us formulate an inference system for first-order logic that is suitable for computational implementation.

The first-order languages we have so far defined have an obvious expressive shortcoming: we have no way to assert that two terms denote the same entity. We will need to be able to express such identities in Chapter ??, when we link Discourse Representation Theory with first-order logic. So what are we to do?

Actually, the solution is straightforward. Given any language of first-order logic (with or without function symbols) we can turn it into a first-order language *with equality* by adding the special two place relation symbol  $=$ . We use this relation symbol in the natural infix way: that is, if  $\tau_1$  and  $\tau_2$  are terms then we write  $\tau_1 = \tau_2$  rather than the rather ugly  $=(\tau_1, \tau_2)$ . Beyond this notational convention, there's nothing more to say about the syntax of  $=$ ; it's just a two place relation symbol. But what about its semantics?

Here matters are more interesting. Although, syntactically,  $=$  is just a 2-place relation symbol, it is a very special one. In fact (unlike LOVES, or HATES, or any other two place relation symbol) we are *not* free to interpret it how we please. In fact, given any model  $\mathbf{M}$ , any assignment  $g$  in  $\mathbf{M}$ , and any terms  $\tau_1$  and  $\tau_2$ , we shall insist that

$$\mathbf{M}, g \models \tau_1 = \tau_2 \text{ iff } I_F^g(\tau_1) = I_F^g(\tau_2).$$

That is, the atomic formula  $\tau_1 = \tau_2$  is satisfied if and only if  $\tau_1$  and  $\tau_2$  have exactly the same interpretation. That is,  $=$  really means equality. In fact,  $=$  is usually regarded as a *logical* symbol on a par with  $\neg$  or  $\forall$ , for like these symbols it has a fixed interpretation, and a semantically fundamental one at that.

## 1.2 A Simple Model Checker

We will now implement a simple first-order model checker in Prolog. The checker will take the Prolog representation of a model and the Prolog representation of a formula and test whether or not the formula is satisfied in the model. (Actually, to keep things simple, we are only going to work with exact models, and we are not going to deal with function symbols or equality.) We will learn two important lessons from this exercise:

1. By making use of Prolog variables to represent first-order variables, it is easy to implement the satisfaction definition. This is because Prolog's built-in unification and backtracking mechanisms can take care—more or less automatically—of the process of assigning values to variables.
2. On the other hand, this simple strategy has its dangers: as we shall see, the obvious implementation is incorrect. We demonstrate some of its shortcomings and show how to correct them in the next section.

How should we implement such a model checker? We have four principal tasks: deciding how to represent vocabularies, deciding how to represent models, deciding how to represent formulas, and specifying how (representations of) formulas are to be evaluated in (representations of) models. The representations introduced here will be used throughout the book.

## Representing Vocabularies

Vocabularies will be represented as Prolog databases. Let's consider an example. Suppose we are working with the following vocabulary:

```
{ (LOVE,2), (HATE,2),  
  (CUSTOMER,1), (ROBBER,1),  
  (MIA,0), (VINCENT,0),  
  (HONEY-BUNNY,0), (PUMPKIN,0) }
```

This would be represented by the following database:

```
relation(love,2).      constant(mia).  
relation(hate,2).      constant(vincent).  
relation(customer,1).  constant(honey_bunny).  
relation(robber,1).    constant(pumpkin).
```

This should be self explanatory: the database simply lists the relation symbols in the vocabulary (together with their arity), and the constant symbols. Both relation symbols and constant symbols are represented by Prolog atoms in the obvious way.

## Representing Models

Suppose we have fixed our vocabulary—for example, suppose we've decided to work with the vocabulary just given. How should we represent models of this vocabulary in Prolog?

Actually, this is an impossibly difficult question. We don't have the remotest chance of dealing with *all* models of this vocabulary, for there are models of this vocabulary based on *any* non-empty domain  $D$  whatsoever. In particular, there are lots of *infinite* models. Now, it is possible to give useful finite representations of some infinite models—but most are too big and too unruly to be worked with computationally. Hence we shall confine our attention to *finite* models of this vocabulary. In addition, matters are simpler if we only have to deal with *exact* models. (Recall that an exact model is a model over a vocabulary containing constants such that every element in the model is named by exactly one constant.) So, let's rephrase our question: how should we represent the finite exact models over the above vocabulary?

Here is an example of how we shall do it:

```
[customer(vincent),customer(mia),  
  robber(honey_bunny),robber(pumpkin),  
  loves(pumpkin,honey_bunny)]
```

Fairly obviously, this list represents a model in which both Vincent and Mia are customers, both Pumpkin and Honey Bunny are robbers, and Pumpkin loves Honey Bunny. But it is important to be aware that other properties are *implicitly* recorded. For example, no facts about the *hate* relationships are given—and *hate* is one of the relation symbols in our vocabulary. This is Prolog's way of recording the fact that the binary relation *hate* is empty; in this little world, nobody hates anybody. Moreover, although Pumpkin loves Honey Bunny, he doesn't love himself nor anybody else, for no such facts are recorded. In fact, no other loving relationships at all hold. Thus, by explicitly listing positive information, and *implicitly* listing negative information, we have completely described a unique exact model over this vocabulary.

Here's a second example, again over the same vocabulary.

```
[customer(vincent),  
  robber(honey_bunny),robber(pumpkin),  
  loves(pumpkin,honey_bunny)]
```

Now for a trick question: how many individuals are there in the domain of the model that this Prolog term represents? The answer is *four*. If you thought the answer was three—because only Vincent, Pumpkin and Honey Bunny are explicitly mentioned—you haven't properly grasped the role played by the constants listed in the vocabulary. In *any* model of this vocabulary there is an individual that corresponds to Mia. As it happens, in this particular model no positive facts are listed about Mia—but lots of negative facts about Mia are implicitly given. For example, Mia is neither a customer nor a robber (perhaps Mia is a waitress), and Mia neither loves nor hates anyone or anything, and is not loved or hated by anyone or anything.

In short, be careful. The list of constants in the vocabulary plays an important role for us: it tells us exactly how many individuals there are in any exact model of that vocabulary, namely one and only one for each constant. Indeed, we can think of the constants listed in the vocabulary as simply *being* the domain of quantification of exact models.

**Exercise 1.2.1** Give the set theoretic description of the models that the two Prolog terms given above represent.

**Exercise 1.2.2** Suppose we are working with the following vocabulary:

$$\{ (\text{WORKS-FOR}, 2), \\ (\text{BOXER}, 1), (\text{PROBLEM-SOLVER}, 1), \\ (\text{THE-WOLF}, 0), (\text{MARSELLUS}, 0), (\text{BUTCH}, 0) \}$$

First, represent this vocabulary as a Prolog database. Then, represent each of the following two (exact) models ( $D, F$ ) over this vocabulary as Prolog terms.

1.  $D = \{d_1, d_2, d_3\}$ ,  
 $F(\text{THE-WOLF}) = d_1$ ,  
 $F(\text{MARSELLUS}) = d_2$ ,  
 $F(\text{BUTCH}) = d_3$ ,  
 $F(\text{BOXER}) = \{d_3\}$ ,  
 $F(\text{PROBLEM-SOLVER}) = \{d_1\}$ .
2.  $D = \{\text{entity-1}, \text{entity-2}, \text{entity-3}\}$   
 $F(\text{THE-WOLF}) = \text{entity-3}$ ,  
 $F(\text{MARSELLUS}) = \text{entity-1}$ ,  
 $F(\text{BUTCH}) = \text{entity-2}$ ,  
 $F(\text{BOXER}) = \{\text{entity-2}, \text{entity-3}\}$ ,  
 $F(\text{PROBLEM-SOLVER}) = \{\text{entity-2}\}$ ,  
 $F(\text{WORKS-FOR}) = \{(\text{entity-3}, \text{entity-1}), (\text{entity-2}, \text{entity-1})\}$ .

**Exercise 1.2.3** Write a Prolog program which when given a vocabulary, and a list, determines whether or not the list represents an (exact) model over that vocabulary. Can your program be used to generate all the exact models over that vocabulary? If not, write a program that can.

## Representing Formulas

Let us now decide how to represent first-order formulas (for languages without function symbols or equality) in Prolog. The first (and most fundamental) decision is how to represent first-order variables. We make the following choice:

*First-order variables will be represented by Prolog variables.*

As has already been mentioned, this decision will enable us to implement a model checker very simply—but it will also give rise to a number of problems.

Next, we must decide how to represent the non-logical symbols. We do so in the obvious way: a first-order constant  $c$  will be represented by the Prolog atom `c`, and a first-order relation symbol  $R$  will be represented by the Prolog atom `r`.

Given this convention, it is obvious how atomic formulas should be represented. For example, `LOVE(VINCENT,MIA)` would be represented by the Prolog term `love(vincent,mia)`, and `HATE(BUTCH,X)` would be represented by `hate(butch,X)`. Note that first-order atomic sentences (for example `BOXER(BUTCH)`) are represented by exactly the same Prolog term (namely `boxer(butch)`) that is used to represent the fact that Butch is a boxer in our Prolog representation of models. This will enable us to give a simple implementation of the satisfaction clause for atomic formulas.

Next the Booleans. The symbols

`&`          `v`          `>`          `~`

will be used to represent the connectives  $\wedge$ ,  $\vee$ ,  $\rightarrow$ , and  $\neg$  respectively. The following Prolog code ensure that these connectives have their usual precedences:

```
:- op(900,yfx,>).      % implication
:- op(850,yfx,v).      % disjunction
:- op(800,yfx,&).       % conjunction
:- op(750, fy,~).      % negation
```

Finally, we must decide how to represent the quantifiers. Suppose *formula* is a first-order formula, and `Formula` is its representation as a Prolog term. Then  $\forall x \text{ formula}$  will be represented as

`forall(X,Formula)`

and  $\exists x \text{ formula}$  will be represented as

`exists(X,Formula)`

## Semantic Evaluation

We now turn to the fourth and final task: evaluating (representations of) formulas in (representations of) models. The predicate which carries out the task is called `satisfy/2`,

and the clauses of `satisfy/2` mirror the first-order satisfaction definition in a fairly natural way.

The clause which evaluates (representations of) atomic formulas is:

```
satisfy(Formula,Model):-  
    member(Formula,Model).
```

The `member/2` predicate is one of the predicates in the library `comsemPredicates.pl`. It succeeds if its first argument, any Prolog term, is a member of its second argument, which has to be a list. It is defined as follows:

```
member(X,[X|_]).  
member(X,[_|L]):-  
    member(X,L).
```

Hence an atomic formula is true if and only if that formula is one of the facts recorded in the list `Model`.

Now for Boolean combinations of formulas.

```
satisfy(Formula1 & Formula2,Model):-  
    satisfy(Formula1,Model),  
    satisfy(Formula2,Model).  
  
satisfy(Formula1 v Formula2,Model):-  
    satisfy(Formula1,Model);  
    satisfy(Formula2,Model).  
  
satisfy(Formula1 > Formula2,Model):-  
    satisfy(Formula2,Model);  
    \+ satisfy(Formula1,Model).  
  
satisfy(~ Formula,Model) :-  
    \+ satisfy(Formula,Model).
```

These mirror the first-order satisfaction definition in an obvious way. However note that in the clauses for `>` and `~` we have made use of Prolog negation (that is, negation as failure). This is a simple and natural thing to do, but as we shall see in the next section, it can interact with our use of Prolog variables to represent first-order variables in unexpected—and unintended—ways.

Finally come the quantifier clauses. The one for the existential quantifier couldn't be simpler:

```
satisfy(exists(X,Formula),Model):-
    constant(X),
    satisfy(Formula,Model).
```

That is, the program unifies  $X$  to some entity in the model (recall that because we are working with exact models, the entities we are talking about are essentially the constants) and then tries evaluating  $Formula$  in  $Model$ . If  $Formula$  is *not* satisfied in  $Model$  the program will backtrack and unify  $X$  to another entity (if this is still possible) and then evaluate the formula again. Either it eventually succeeds (which means that there exists an entity in the model that does satisfy  $Formula$ ), or it doesn't (which means there isn't). Clearly, this captures the semantics of the existential quantifier. Moreover it does so in a straightforward way: Prolog's unification and backtracking mechanisms are being used to simulate the process of assigning values to first-order variables.

At first glance, the following clause for the universal quantifier may look a little strange—but recall that  $\forall x\phi$  is logically equivalent to  $\neg\exists x\neg\phi$  (the reader was asked to show this in Exercise 1.1.4). The following clause simply represents this equivalence in Prolog (using negation as failure), and makes use of Prolog's unification and backtracking mechanisms in much the same way as the clause for `exists` does.

```
satisfy(forall(X,Formula),Model):-
    satisfy(~ exists(X, ~ Formula),Model).
```

So, it's time to start checking models. Here are some examples of models over our original vocabulary:

```
example(1,[customer(mia),customer(vincent),
           robber(pumpkin),robber(honey_bunny),
           love(pumpkin,honey_bunny)]).

example(2,[customer(mia),
           robber(pumpkin),robber(honey_bunny),
           love(pumpkin,honey_bunny)]).

example(3,[customer(mia),customer(vincent),
           robber(pumpkin),robber(honey_bunny),
           love(pumpkin,honey_bunny),love(mia,vincent)]).
```

And here is a driver predicate which evaluates a formula on the desired example model:

```
evaluate(Formula,Example):-
    example(Example,Model),
    satisfy(Formula,Model).
```

**Exercise 1.2.4** Systematically test the model checker on these models. Are the results always what you expected? If not, why not?

## 1.3 Some Refinements

As the reader who has tested the model checker will have learned, the current version of the model checker is far from satisfactory. In fact, it does quite a number of silly things. Let's try pinning down the various problems.

### First Problem

What happens if we ask Prolog to evaluate a *variable* in one of our example models:

```
?- evaluate(X,1).
```

This is a perfectly reasonable query; in fact there are two motives we might have for making it. The first is simply to ask Prolog to generate a formula that can be evaluated in model 1. The second—recall that we decided to use Prolog variables for representing first-order variables—is to check whether our predicate successfully recognizes that a variable is not a formula, and hence cannot be evaluated. Both are good ideas, but neither works as planned, for the program immediately goes into an infinite loop.

**Exercise 1.3.1** Why does the program get in an infinite loop when posing the above query? If this is not clear, perform a trace.

To solve this problem, we will simply reject queries that try to evaluate variables. This is easily done by adding a filtering clause to the evaluation predicate:

```
evaluate(Formula,Example):-
    \+ var(Formula),
    example(Example,Model),
    satisfy(Formula,Model).
```

This ensures that `evaluate` only succeeds if `Formula` is not a variable. However, this problem is deeper and more structural, and this proposed solution is not satisfactory. To find out why you might try the following exercise.

**Exercise 1.3.2** [Easy] Try the above evaluation predicate on formulas that contain subformulas that are represented as Prolog variables, for example the formula `exists(X,robber(X) > Y)`. What happens and why?

**Exercise 1.3.3** [Hard] Try to modify the program in such a way that it generates formulas that can be evaluated in a specified model when given the query `evaluate(X,1)` (for example model 1).

## Second Problem

The second problem has to do with the way negation as failure interacts with our use of Prolog variables to represent first-order variables.

Suppose we evaluate

```
customer(X)
```

in example 1. That is, we're asking whether it is possible to assign a value to the free variable that satisfies the formula; thus Prolog's task is to find an entity in this model that is a customer. In example 1, of course, it finds two: Mia and Vincent.

Now suppose we evaluate

```
~ customer(X)
```

in example 1. That is, we're again asking whether it is possible to assign a value to the free variable that satisfies the formula, thus Prolog's task is to find an entity in this model that is *not* a customer. In example 1, of course, there are two non-customers, namely Honey Bunny and Pumpkin.

However, Prolog wrongly answers `no`. This is because we defined the interpretation of negated clauses using negation as failure. As `customer(X)` is satisfiable, Prolog (incorrectly) decides that `~ customer(X)` is not satisfiable.

This is unacceptable and has to be fixed. But before doing so, let's look at another problem.

## Third Problem

We run into problems if we ask our model checker to verify formulas using completely new non-logical vocabulary. For example, suppose we try evaluating the atomic formula

```
tasty(royale_with_cheese)
```

in any of example models. Then our model checker will say `no`. This response is *not*, strictly speaking, correct. Formally the satisfaction relation is not defined between formulas and

models of different vocabularies. The correct response of our model checker would be to throw out this formula and say something like “Hey, I don’t know anything about these symbols!”.

This example may not strike the reader as too problematic—but worse is in store. If we evaluate

```
~ tasty(royale_with_cheese)
```

in any of example models they will return the answer **yes**! This happens because we used negation as failure to define the evaluation clause for negated formulas. Clearly this needs fixing.

However the problem is not particularly deep; the solution is simply to be explicit about what a well formed formula over a given vocabulary is. That is, we should make use of the information in the vocabulary about which relation symbols we are working with (and, of course, what their arities are), which constants we have, and explicitly state which combinations of these symbols are well formed. (Note that at present we’re not making *any* use of the information stored in our vocabulary. It’s hardly surprising that we’re having these difficulties.) Our driver should check that any sequence of symbols it has to evaluate really is a well formed combination of the chosen relation and constant symbols—and it should refuse to evaluate anything that isn’t.

Now, to do this we’re going to have to recursively work through the structure of the input formula—so this gives us a good opportunity to solve the second problem as well. In fact, we shall define a predicate **sentence/2** whose primary task is to transform a formula with free variables into a sentence by substituting constants of the vocabulary for occurrences of free variables. While doing this it will check that the Prolog terms it encounters represent well formed formulas built out of the given vocabulary. Thus **sentence/2** will solve the second and third problems simultaneously.

We define **sentence/2** as follows. Its first argument will be a list; we use it to keep track of all the bound variables we have encountered in the course of analysis. The second argument is a formula.

The first clause deals with evaluating uninstantiated Prolog variables. This immediately causes failure, and therefore deals with the first problem. (We use the **!, fail** combination to exclude all other clauses for possible solutions.)

```
sentence(_,Var):-
    var(Var), !, fail.
```

The required clauses for non-atomic formulas are fairly obvious:

```

sentence(Bound,forall(X,Formula)):-
    var(X),
    sentence([X|Bound],Formula).

sentence(Bound,exists(X,Formula)):-
    var(X),
    sentence([X|Bound],Formula).

sentence(Bound,Formula1 > Formula2):-
    sentence(Bound,Formula1),
    sentence(Bound,Formula2).

sentence(Bound,Formula1 & Formula2):-
    sentence(Bound,Formula1),
    sentence(Bound,Formula2).

sentence(Bound,Formula1 v Formula2):-
    sentence(Bound,Formula1),
    sentence(Bound,Formula2).

sentence(Bound,~ Formula):-
    sentence(Bound,Formula).

```

Note the way the clauses for `forall` and `exists` push the variable currently being bound onto the bound variable list (after first testing that it really *is* a legitimate Prolog variable).

But that's the easy part. The real work is done at the atomic level, where we substitute constants for free variables. Here's the code:

```

sentence(Bound,Formula):-
    compose(Formula,Symbol,Arguments),
    length(Arguments,Arity),
    relation(Symbol,Arity),
    goodArguments(Bound,Arguments).

goodArguments(_Bound,[]).
goodArguments(Bound,[Arg|Others]):-
    member(Arg,Bound),
    Var==Arg,!,
    goodArguments(Bound,Others).
goodArguments(Bound,[Arg|Others]):-
    constant(Arg),
    goodArguments(Bound,Others).

```

Here `compose/3` is a predicate in the library file `comsemPredicates.pl`. It is defined as follows:

```
compose(Term,Symbol,ArgList):-
    Term =.. [Symbol|ArgList].
```

In short, `compose/3` uses the built in Prolog `=..` functor to flatten a term into a list.

Thus, at the base of the recursion, `sentence/2` uses `compose/3` to take the atomic formula apart into a list. It then checks that the first item on the list really is one of our relation symbols, and that it has the correct number of arguments. If everything is satisfactory, it hands the list over to `goodArguments/2`. This predicate recursively checks through the tail of the list (that is, the terms used to build the atomic formula). If one of these items is a Prolog variable, it checks to see whether it is listed in `Bound`. If it is, that's fine; we are dealing with a bound variable and don't have to worry. On the other hand, if it's *not* on this list, we have found a free variable which needs replacing by a constant. The call `constant(Arg)` unifies it to one of the constants in the vocabulary. Note that on backtracking this call will successively unify the free variable to every constant in the vocabulary. In effect this code is taking advantage of the similarity between free variables and constants discussed in Exercise 1.1.2; as we observed, when working with exact models, every formula is equivalent to a sentence.

And that's it. It only remains to write a new driver which puts these predicates to work. We'll implement the driver using two clauses. The first clause deals with formulas that are sentences, the second clause with formulas that aren't sentence (in that case it alerts the user with a message saying that the formula cannot be evaluated).

```
evaluate(Formula,Example):-
    sentence([],Formula),
    example(Example,Model),
    satisfy(Formula,Model).

evaluate(Formula,_Example):-
    \+ sentence([],Formula),
    nl,write('Not a wff over the given vocabulary.'),
    nl,write('Cannot be evaluated.'),nl.
```

It should be clear that this revised version of our evaluation predicate fixes the third problem.

This is a much cleaner model checker. Simply by making use of the information stored in vocabularies it tidies up a lot of silly problems in one fell swoop; indeed, it even tidies up a problem not mentioned in the text. It is important that you understand what is going on here, so we suggest you work through the following problems right away.

**Exercise 1.3.4** Try out the new evaluation predicate on the query `~ customer(X)`. Why has problem 2 vanished?

**Exercise 1.3.5** Suppose we continue to work with the same vocabulary and we add the model `[]` to our list of examples. That is, we add the model that contains no positive information about any of our four individuals. Does the first version of `evaluate/2` handle queries about this model correctly? Does the revised version? Explain why.

## Another Problem

Our new evaluation predicate takes care of the sillier shortcomings of our first version, and we won't bother making any further improvements. Nonetheless, the reader should realize that it is still not perfect. There is another problem, due solely to our decision to use Prolog variables to represent first-order variables.

Although more complex than the original version, the new `evaluate/2` is a fairly simple predicate. This is because all the real work of variable handling is being taken care of—more or less automatically—by Prolog's in-built unification and backtracking mechanisms. But in a sense, we've cheated. Neither the original `evaluate` nor its successor really understand how to treat free and bound variables at all.

An example should make this clear. In first-order logic the formulas

$$\exists x (\text{CUSTOMER}(x)) \wedge \exists y (\text{ROBBER}(y))$$

and

$$\exists x (\text{CUSTOMER}(x)) \wedge \exists x (\text{ROBBER}(x))$$

are equivalent. Now, their Prolog representations are

```
exists(X,customer(X)) & exists(Y,robber(Y))
```

and

```
exists(X,customer(X)) & exists(X,robber(X))
```

respectively. However

```
?- evaluate(exists(X,customer(X)) & exists(Y,robber(Y)),1).
```

succeeds (it returns all four of the successful ways of instantiating  $X$  and  $Y$ ) while

```
?- evaluate(exists(X,customer(X)) & exists(X,robber(X)),1).
```

returns `no`.

The difficulty is easy to spot. Prolog doesn't know that the  $X$  in `customer(X)` is intended to play a different role than the  $X$  in `robber(X)`; it will always instantiate them to the same thing.

But fortune seems on our side, as there is a simple Prolog trick that helps us here. The problem lies in instantiating bound variables by one of the constants of our vocabulary using `constant/1` in the predicate `satisfy/2`. Here is where this happens (and note that this is the *only* spot where variables get instantiated):

```
satisfy(exists(X,Formula),Model):-
    constant(X),
    satisfy(Formula,Model).
```

Once  $X$  gets instantiated, it remains instantiated. And that's what causes the problem. A simple Prolog-remedy is to use double negation, which ensures that variables inside it are not instantiated (in fact, they are only instantiated during the proof of the negation). Here is a revised clause for handling the existential quantifier:

```
satisfy(exists(X,Formula),Model):-
    \+ \+ (constant(X), satisfy(Formula,Model)).
```

However, this trick doesn't cover all problems of binding. Here is an example of a formula that doesn't get evaluated in model 1 although it's a perfectly fine formula in first-order logic (and satisfied in our example model 1!).

$$\exists x (\text{CUSTOMER}(x) \wedge \exists x \text{ROBBER}(x))$$

The moral is clear. We should either write a better evaluation predicate that guards against this shortcoming (the reader is asked to do this as an exercise) or we should ensure that different occurrences of quantifiers bind distinct variables. More generally, it is clear that 'clever' Prolog solutions to variable manipulation problems require careful scrutiny; we will see another example in the following chapter when we implement  $\beta$ -reduction.

**Exercise 1.3.6** [easy] Write a predicate which when given a formula, checks for reused variables. Redefine the predicate `evaluate` that filters out such sentences.

**Exercise 1.3.7** [hard] Redefine the predicate `satisfy/2` such that it uses explicit assignment functions.

## 1.4 First-Order Logic and Natural Language

### Expressivity Problems

(to be provided)

### Representational Problems

(to be provided)

#### Software Summary of Chapter 1

`modelChecker.pl` The file that contains the code for the simple model checker for first-order logic. This version neither takes care of free variables, nor does it consult the vocabulary to exclude ill-formed formulas. (page 209)

`modelChecker2.pl` This file contains the code for the revised model checker for first-order logic. This version takes care of free variables and excludes ill-formed formulas. (page 211)

`exampleModels.pl` Contains the specification of the vocabulary and a few example models. (page 214)

## Notes

There are many good introductions to first-order logic, and the best advice we can give the reader is to spend some time browsing in a library to see what's on offer. That said, there's three references we particularly recommend. For an unhurried introduction that motivates the subject linguistically, try the first volume of Gamut 1991a. For a wide-ranging discursive overview, we recommend Hodges 1983. This survey article covers a lot of ground—from truth tables to Lindström's celebrated characterization of first-order logic. Parts of the article are quite technical, but, by and large, it's the sort of article that many readers will enjoy browsing through. On the other hand, the reader who wants a more focussed approach may prefer Enderton 1972. This is a good, solid, and extremely readable introduction to first-order logic.

# Chapter 2

## Lambda Calculus

Now that we know something of first-order logic and how to work with it in Prolog, it is time to turn to the first major theme of the book, namely:

*How can we automate the process of associating semantic representations with natural language expressions?*

In this chapter we explore the issue concretely. We proceed by trial and error. We first write a simple Prolog program that performs the task in a limited way. We note where it goes wrong, and why, and develop a more sophisticated alternative. These experiments lead us, swiftly and directly, to formulate a version of the *lambda calculus*. The lambda calculus is a tool for controlling the process of making substitutions. With its help, we will be able to describe, neatly and concisely, how semantic representations should be built. The lambda calculus is one of the main tools used in this book, and by the end of the chapter the reader should have a reasonable grasp of why it is useful to computational semantics and how to work with it in Prolog.

### 2.1 Compositionality

Given a sentence of English, is there a systematic way of constructing its semantic representation? This question is far too general, so let's ask a more specific one: is there a systematic way of translating simple sentences such as 'Vincent likes Mia' and 'A woman snorts' into first-order logic?

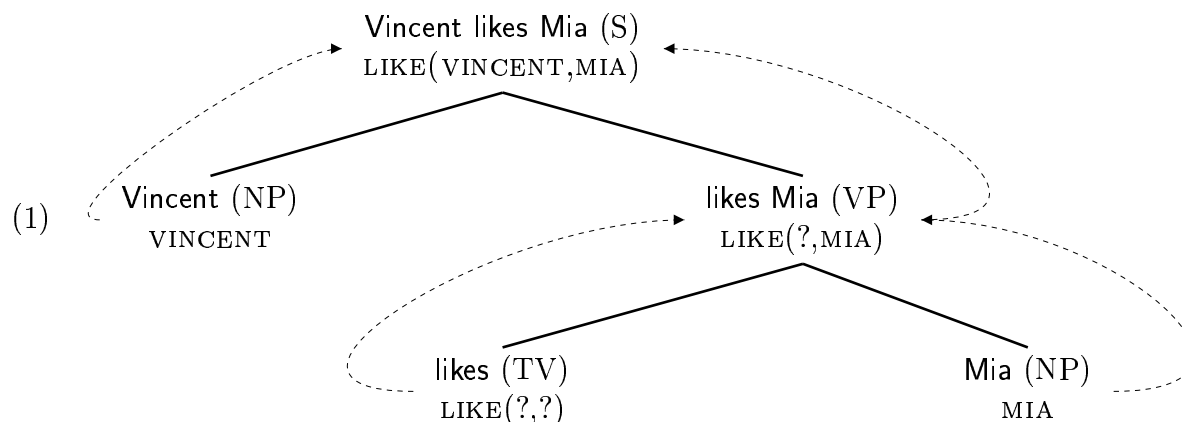

The key to answering this is to be more precise about what we mean by 'systematic'. Consider 'Vincent likes Mia'. Its semantic content is at least partially captured by the first-order formula `LIKE(VINCENT,MIA)`. Now, the most basic observation we can make about systematicity is the following: the proper name 'Vincent' contributes the constant

VINCENT to the representation, the transitive verb ‘likes’ contributes the relation symbol LIKE, and ‘Mia’ contributes MIA.

This first observation is important, and by no means as trivial as it may seem. If we generalize it to the claim that the words making up a sentence contribute *all* the bits and pieces needed to build the sentence’s semantic representation, we have formulated a principle that is a valuable guide to the complexities of natural language semantics. The principle is certainly plausible. Moreover, it has the advantage of forcing us to face up to a number of non-trivial issues sooner rather than later (for example, what exactly does the determiner ‘every’ contribute to the representation of ‘Every woman loves a boxer’?).

Nonetheless, though important, this principle doesn’t tell us everything we need to know about systematicity. For example, from the symbols LIKE, MIA and VINCENT we can also form LIKE(MIA,VINCENT). Why don’t we get this (incorrect) representation when we translate ‘Vincent likes Mia’? What exactly is it about the sentence ‘Vincent likes Mia’ that forces us to translate it as LIKE(VINCENT,MIA)? Note that the answer “But ‘Vincent likes Mia’ means LIKE(VINCENT,MIA), stupid!”, which in many circumstances would be appropriate, isn’t particularly helpful here. Computers *are* stupid. We can’t appeal to their semantic insight, because they don’t have any. If we are to have any hope of automating semantic construction, we must find another kind of answer.

The missing ingredient is a notion of *syntactic structure*. ‘Vincent likes Mia’ isn’t just a string of words: it has a hierarchical structure. In particular, ‘Vincent likes Mia’ is an S (sentence) that is composed of the subject NP (noun phrase) ‘Vincent’ and the VP (verb phrase) ‘likes Mia’. This VP is in turn composed of the TV (transitive verb) ‘likes’ and the direct object NP ‘Mia’. Given this hierarchy, it is easy to tell a coherent story—and indeed, to draw a convincing picture—about why we should get the representation LIKE(VINCENT,MIA), and not anything else:

Why is MIA in the second argument slot of LIKE? Because, when we combine a TV with an NP to form a VP, we have to put the semantic representation associated with the NP (in this case, MIA) in the *second* argument slot of the VP’s semantic representation (in

this case, `LIKE(?,?)`). Why does VINCENT have to go in the *first* argument slot? Because this is the slot reserved for the semantic representations of NPs that we combine with VPs to form an S. More generally, given that we have some reasonable syntactic story about what the pieces of the sentences are, and which pieces combine with which other pieces, we can try to use this information to explain how the various semantic contributions have to be combined. In short, one reasonable explication of ‘systematicity’ is that it amounts to using the additional information provided by syntactic structure to spell out exactly how the semantic contributions are to be glued together.

Our discussion has led us to one of the key concepts of contemporary semantic theory: *compositionality*. Suppose we have some sort of theory of syntactic structure. It doesn’t matter too much what sort of theory it is, just so long as it is hierarchical in a way that ultimately leads to the lexical items. (That is, our notion of syntactic structure should allow us to classify the sentence into subparts, sub-subpart, and sub-sub-subparts, ..., and so on—ultimately into the individual words making up the sentence.) Such structures make it possible to tell an elegant story about where semantic representations come from. Ultimately, semantic information flows from the lexicon, thus each lexical item is associated with a representation. How is this information combined? By making use of the hierarchy provided by the syntactic analysis. Suppose the syntax tells us that some kind of sentential subpart (a VP, say) is decomposable into two sub-subparts (a TV and an NP, say). Then our task is to describe how the semantic representation of the VP subpart is to be built out of the representation of its two sub-subparts. If we succeed in doing this for all the grammatical constructions covered by the syntax, we will have given a *compositional semantics* for the language under discussion (or at least, for that fragment of the language covered by our syntactic analysis).

Compositionality is a simple and natural concept that underlies most work in natural language semantics and the semantics of programming languages. Nonetheless, in spite of its simplicity, it raises a number of interesting issues. For example, is every ‘systematic’ semantics a compositional one? In Part II we discuss the standard top-down algorithm for Discourse Representation Theory. This algorithm is a systematic approach to semantic construction (under any reasonable interpretation of the word ‘systematic’) but many semanticists have argued that it is not truly compositional.

## Syntax via Definite Clause Grammars

So, is there a systematic way of translating simple sentences such as ‘Vincent likes Mia’ and ‘A woman snorts’ into first-order logic? We don’t yet have a method, but at least we now have a plausible strategy for finding one. We need to:

**Task 1** Specify a reasonable syntax for the fragment of natural language of interest.

**Task 2** Specify semantic representations for the lexical items.

**Task 3** Specify the translation compositionally. That is, we should specify the translation of all expressions in terms of the translation of their parts, where ‘parts’ refers to the substructure given to us by the syntax.

Moreover, all three tasks need to be carried out in a way that leads naturally to computational implementation.

As this is a book on computational semantics, tasks 2 and 3 are where our real interests lie, and most of our energy will be devoted to them. But since compositional semantics presupposes syntax, we need a way of handling task 1. What should we do?

We have opted for a particularly simple solution: in this book the syntactic analysis of a sentence will be a tree whose non-leaf nodes represent *complex syntactic categories* (such as S, NP and VP) and whose leaves represent *lexical items* (these are associated with *basic syntactic categories* such as noun, transitive verb, determiner, proper name and intransitive verb). The tree the reader has just seen is a typical example. This approach has an obvious drawback (namely, the reader won’t learn anything interesting about syntax) but it also has an important advantage: we will be able to make use of Definite Clause Grammars (DCGs), the in-built Prolog mechanism for grammar specification.

Here is a DCG for the fragment of English we shall use in our initial semantic construction experiments. (This DCG, decorated with semantic construction code, can be found in `experiment1.pl` and `experiment2.pl`. The reader unfamiliar with DCGs is advised to consult Appendix D right away, as otherwise this chapter will shortly stop making much sense.)

```

s --> np, vp.           noun --> [woman].
np --> pn.              noun --> [foot,massage].
np --> det, noun.       vp --> iv.
pn --> [vincent].       vp --> tv, np.
pn --> [mia].           iv --> [walks].
det --> [a].            tv --> [loves].
det --> [every].        tv --> [likes].

```

This grammar tells us how to build certain kinds of sentences (`s`) out of noun phrases (`np`), verb phrases (`vp`), proper names (`pn`), determiners (`det`), nouns (`noun`), intransitive verbs (`iv`), and transitive verbs (`tv`), and gives us a tiny lexicon to play with. For example, the grammar accepts the simple sentence

Vincent walks

because ‘Vincent’ is declared as a proper name, and proper names are noun phrases according to this grammar; ‘walks’ is an intransitive verb, and hence a verb phrase; and sentences can consist of a noun phrase followed by a verb phrase.

But the real joy of DCGs is that they provide us with a lot more than a natural notation for specifying grammars. Because they are part and parcel of Prolog, we can actually compute with them. For example, by posing the query

```
s([mia,likes,a,foot,message],[])
```

we can test whether ‘Mia likes a foot message’ is accepted by the grammar, and the query

```
s(X,[])
```

generates all grammatical sentences.

**Exercise 2.1.1** How many sentences are accepted by this grammar? How many noun phrases? How many verb phrases? Check your answer by generating the relevant items.

With a little effort, we can do a lot more. In particular, by making use of extra arguments (again, see Appendix D if you’re uncertain what this means) we can associate semantic representations with lexical items very straightforwardly. The normal Prolog unification mechanism then gives us the basic tool needed to combine semantic representations, and to pass them up towards sentence level. In short, working with DCGs both frees us from having to implement parsers, and makes available a powerful mechanism for combining representations, so we’ll be able to devote our attention to semantic construction.

The semantic construction methods discussed in this book are compatible with a wide range of syntactical theories. In essence, this book is about exploiting the recursive structure of trees to build representations compositionally; where the trees actually come from is relatively unimportant. We have chosen to fill in the syntactical ‘black box’ using DCGs—but a wide range of more sophisticated options is available and we urge our readers to experiment.

## 2.2 Two Experiments

How can we systematically associate first-order formulas with the sentences produced by our little grammar? Let’s just plunge in and try, and see how far our knowledge of DCGs and Prolog will take us.

### Experiment 1

First the lexical items. We need to associate ‘Vincent’ with the constant `VINCENT`, ‘Mia’ with the constant `MIA`, ‘walks’ with the unary relation symbol `WALK`, and ‘loves’ with

the binary relation symbol `LOVE`. The following piece of DCG code makes these associations. Note that the arity of `walk` and `love` are explicitly included as part of the Prolog representation.

```
pn(vincent)--> [vincent].

pn(mia)--> [mia].

iv(snort(_))--> [snorts].

tv(love(_, _))--> [loves].
```

How do we build semantic representations for sentences? Let's first consider how to build representations for quantifier-free sentences such as 'Mia loves Vincent'. The main problem is to steer the constants into the correct slots of the relation symbol. (Remember, we want 'Vincent loves Mia' to be represented by `LOVE(VINCENT, MIA)`, not `LOVE(MIA, VINCENT)`.) Here's a first (rather naive) attempt. Let's directly encode the idea that when we combine a TV with an NP to form a VP, we have to put the semantic representation associated with the NP in the second argument slot of the VP semantic representation, and that we use the first argument slot for the semantic representations of NPs that we combine with VPs to form Ss.

Recall that Prolog has a built in predicate `arg/3` such that `arg(N,P,I)` is true if `I` is the `N`th argument of `P`. This is a useful tool for manipulating pieces of syntax, and with its help we can cope with simple quantifier free sentences rather easily. Here's the needed extension of the DCG:

```
s(Sem)--> np(SemNP), vp(Sem),
{
    arg(1,Sem,SemNP)
}.

np(Sem)--> pn(Sem).

vp(Sem)--> tv(Sem), np(SemNP),
{
    arg(2,Sem,SemNP)
}.

vp(Sem)--> iv(Sem).
```

These clauses work by adding an extra argument to the DCG (here, the position filled by the variables `Sem` and `SemNP`) to percolate up the required semantic information using

Prolog unification. Note that while the second and the fourth clauses perform only this percolation task, the first and third clauses, which deal with branching rules, have more work to do: they use `arg/3` to steer the arguments into the correct slots. This is done by associating extra pieces of code with the DCG rules, namely `arg(1,Sem,SemNP)` and `arg(2,Sem,SemNP)`. (These are normal Prolog goals, and are added to the DCG rules in curly brackets to make them distinguishable from the grammar symbols.) This program captures, in a brutally direct way, the idea that the semantic contribution of the object NP goes into the second argument slot of TVs, while the semantic contribution of subject NPs belongs in the first argument slot.

It works. For example, if we pose the query:

```
?- s(Sem,[mia,snorts],[]).
```

we obtain the (correct) response:

```
Sem = snort(mia)
```

But this is far too easy—let’s try to extend our fragment with the determiners ‘a’ and ‘every’. First, we need to extend the lexical entries for these words, and the entries for the common nouns they combine with:

```
det(exists(_,&_))--> [a].
```

```
det(forall(_,>_))--> [every].
```

```
noun(woman(_))--> [woman].
```

```
noun(footmassage(_))--> [foot,message].
```

NPs formed by combining a determiner with a noun are called *quantified noun phrases*.

Next, we need to say how the semantic contributions of determiners and noun phrases should be combined. We can do this by using `arg/3` four times to get the instantiation of the different argument positions correct:

```
np(Sem)--> det(Sem), noun(SemNoun),
{
    arg(1,SemNoun,X),
    arg(1,Sem,X),
    arg(2,Sem,Matrix),
    arg(1,Matrix,SemNoun)
}.
```

The key idea is that the representation associated with the NP will be the representation associated with the determiner (note that the `Sem` variable is shared between `np` and `det`), but with this representation fleshed out with additional information from the noun. The Prolog variable `X` is a name for the existentially quantified variable the determiner introduces into the semantic representation; the code `arg(1,SemNoun,X)` and `arg(1,Sem,X)` unifies the argument place of the noun with this variable. The code `arg(2,Sem,Matrix)` simply says that the second argument of `Sem` will be the matrix of the NP semantic representation, and `arg(1,Matrix,SemNoun)` then adds more detail: it says that the first slot of the matrix will be filled in by the semantic representation of the noun. So if we pose the query

```
?- np(Sem,[a,woman],[]).
```

we obtain the response

```
Sem = exists(X,woman(X)&Y)
```

Note that this representation is an *incomplete* first-order formula. We don't yet have a full first-order formula (the Prolog variable `Y` has yet to be instantiated) but we do know that we are existentially quantifying over the set of women.

Given that such incomplete first-order formulas are the semantic representations associated with quantified NPs, it is fairly clear what must happen when we combine a quantified NP with a VP to form an S: the VP must provide the missing piece of information. (That is, it must provide an instantiation for `Y`.) The following clause does this:

```
s(Sem)--> np(Sem), vp(SemVP),
{
  arg(1,SemVP,X),
  arg(1,Sem,X),
  arg(2,Sem,Matrix),
  arg(2,Matrix,SemVP)
}.
```

Unfortunately, while the underlying idea is essentially correct, things have just started going badly wrong. Until now, we've simply been extending the rules of our original DCG with semantic information—and we've already dealt with `s --> np, vp`. If we add this second version of `s --> np, vp` (and it seems we need to) we are duplicating syntactic information. This is uneconomical and inelegant. Worse, this second sentential rule interacts in an unintended way with the rule

```
np(Sem)--> pn(Sem).
```

As the reader should check, as well as assigning the correct semantic representation to ‘A woman snorts’, our DCG also assigns the splendidly useless string of symbols

```
snort(exist(X,woman(X)&Y))
```

But this isn’t the end of our troubles. We already have a rule for forming VPs out of TVs and NPs, but we will need a second rule to cope with quantified NPs in object position, namely:

```
vp(Sem)--> tv(SemTV), np(Sem),
{
    arg(2,SemTV,X),
    arg(1,Sem,X),
    arg(2,Sem,Matrix),
    arg(2,Matrix,SemTV)
}.
```

If we add this rule, we can assign correct representations to all the sentences in our fragment. However we will also produce a lot of nonsense (for example, ‘A woman loves a foot massage’ is assigned four representations, three of which are just jumbles of symbols) and we are being systematically forced into syntactically unmotivated duplication of rules. This doesn’t look promising. Let’s try something else.

**Exercise 2.2.1** The code for experiment 1 is in `experiment1.pl`. Generate the semantic representations of the sentences and noun phrases yielded by the grammar.

## Experiment 2

Although our first experiment was ultimately unsuccessful, it did teach us something useful: to build representations, we need to work with *incomplete* first-order formulas, and we need a way of manipulating the missing information. Consider the representations associated with determiners. In experiment 1 we associated ‘a’ with `exists(,_,&_)`. That is, this determiner contributes the skeleton of a first-order formula whose first slot needs to be instantiated with a variable, whose second slot needs to be filled with the semantic representation of a noun, and whose third slot needs to be filled by the semantic representation of a VP. However in experiment 1 we didn’t manipulate this missing information directly. Instead we took a shortcut: we thought in terms of argument *position* so that we could make use of `arg/3`. Let’s avoid plausible looking short cuts. The idea of missing information is evidently important, so let’s take care to always associate it with an explicit Prolog variable. Perhaps this direct approach will make semantic construction easier.

Let's first apply this idea to the determiners. We shall need three extra arguments: one for the bound variable, one for the contribution made by the noun, and one for the contribution made by the VP. Incidentally, these last two contribution have a standard name: the contribution made by the noun is called the *restriction* and the contribution made by the VP is called the *nuclear scope*. We reflect this terminology in our choice of variable names:

`det(X,Restr,Scope,exists(X,Restr & Scope))--> [a] .`

`det(X,Restr,Scope,forall(X,Restr > Scope))--> [every] .`

But the same idea applies to common nouns, intransitive verbs, and transitive verbs too. For example, instead of associating 'woman' with `woman(_)`, we should state that the translation of 'woman' is `WALK(y)` for some particular choice of variable `y`—and we should *explicitly* keep track of which variable we choose. (That is, although the `y` appears free in `WALK(y)`, we actually want to have some sort of hold on it.) Similarly, we want to associate a transitive verb like 'loves' with `LOVE(y,z)` for some particular choice of variables `y` and `z`, and again, we should keep track of the choices we made. So the following lexical entries are called for:

`noun(X,woman(X))--> [woman] .`

`iv(Y,snort(Y))--> [snorts] .`

`tv(Y,Z,love(Y,Z))--> [loves] .`

Given these changes, we need to redefine the rules for producing sentences and verb phrases.

`s(Sem)--> np(X,SemVP,Sem) , vp(X,SemVP) .`

`vp(X,Sem)--> tv(X,Y,SemTV) , np(Y,SemTV,Sem) .`

`vp(X,Sem)--> iv(X,Sem) .`

The semantic construction rule associated with the sentential rule, for example, tells us that `Sem`, the semantic representation of the sentence, is essentially going to be that of the noun phrase (that's where the value of the `Sem` variable will trickle up from) but that, in addition, the bound variable `X` used in `Sem` must be the same as the variable used in the verb phrase semantic representation `SemVP`. Moreover, it tells us that `SemVP` will be used to fill in the information missing from the semantic representation of the noun phrase.

So far so good, but now we need a little trickery. Experiment 1 failed because there was no obvious way of making use of the semantic representations supplied by quantified noun

phrases and proper names in a single sentential rule. Here we only have a single sentential rule, so evidently the methods of experiment 2 avoid this problem. Here's how it's done:

```
np(X,Scope,Sem)--> det(X,Restr,Scope,Sem), noun(X,Restr).
```

```
np(SemPN,Sem,Sem)--> pn(SemPN).
```

Note that we have given all noun phrases—regardless of whether they are quantifying phrases or proper names—the same arity in the grammar rules. (That is, there really is only *one* `np` predicate in this grammar, not two predicates that happen to make use of the same atom as their functor name.)

It should be clear how the first rule works. The skeleton of a quantified noun phrase is provided by the determiner. The restriction of this determiner is filled by the noun. The resultant noun phrase representation is thus a skeleton with two marked slots: `X` marks the bound variable, while `Scope` marks the missing scope information. This `Scope` variable will be instantiated by the verb phrase representation when the sentential rule is applied.

The second rule is trickier. The vital work is performed by the doubled `Sem` variable. Roughly speaking, when we combine the noun phrase representations formed by this rule with a verb phrase, the effect of this doubling is to ‘move the verb phrase representation rightwards’ so that it occupies the slot that will ultimately be used in forming the sentential semantics. Intuitively, whereas the representation for sentences that have a quantified noun phrase as subject are essentially the subject’s representation filled out by the verb phrase representation, the reverse is the case when we have a proper name as subject. When that happens, the verb phrase is boss. The sentence representation is essentially the verb phrase representation, and the role of the proper name is simply to obediently instantiate the marked verb phrase slot. The rightwards shuffle performed by the doubled variables is the Prolog mechanism which captures this role-reversal.

Our second experiment has fared far better than our first. It is clearly a good idea to explicitly mark missing information; this gives us the control required to fill it in and maneuver it into place. Nonetheless, experiment 2 uses the idea clumsily. Much of the work is done by the rules. These state how semantic information is to be combined, and (as our NP rule for proper names shows) this may require rule-specific Prolog tricks such as variable doubling. Moreover, it is hard to think about the resulting grammar in a modular way. For example, when we explained why the NP rules took the form they do, we did so by explaining what was eventually going to happen when the S rule was used. Now, perhaps we weren’t *forced* to do this—nonetheless, we find it difficult to give an intuitive explanation of our rules on an individual basis.

This suggests we are missing something. Maybe a more disciplined approach to missing information would reduce—or even eliminate—the need for rule-specific combination methods? Indeed, this is exactly happens if we make use of the *lambda calculus*.

**Exercise 2.2.2** Using either pen and paper or a tracer, compare the sequence of variable instantiations this program performs when building representations for ‘Vincent snorts’ and ‘A woman snorts’, and ‘Vincent loves Mia’ and ‘Vincent loves a woman’.

## 2.3 The Lambda Calculus

For present purposes we shall view lambda calculus as a notational extension of first order logic that allows us to bind variables using a new variable binding operator  $\lambda$ . Occurrences of variables bound by  $\lambda$  should be thought of as placeholders for missing information: they *explicitly* mark where we should substitute the various bits and pieces obtained in the course of semantic construction. An operation called  $\beta$ -conversion performs the required substitutions. We suggest that the reader think of the lambda calculus as a special programming language dedicated to a single task: gluing together the items needed to build semantic representations. This glue language turns out to remarkably flexible: it is compatible with the underspecified representations introduced in Chapter 3, and with the Discourse Representation Structures studied in Part II.

The lambda operator marks missing information by binding variables. Here is a simple lambda expression:

$$\lambda x. \text{MAN}(x)$$

Here the prefix  $\lambda x.$  binds the occurrence of  $x$  in  $\text{MAN}(x)$ . We sometimes say that the prefix  $\lambda x.$  *abstracts over* the variable  $x$ . We call expressions with such prefixes *lambda abstractions* (or, more simply, *abstractions*). In our example, the binding of the free  $x$  variable in  $\text{MAN}(x)$  explicitly indicates that  $\text{MAN}$  has an argument slot where we may perform substitutions. More generally, the purpose of abstracting over variables is to mark the slots where we want substitutions to be made.

Concatenation indicates that we wish to perform substitution. We’re using a special symbol “@” to indicate concatenation. Consider the following expression:

$$\lambda x. \text{MAN}(x) @ \text{VINCENT}.$$

This compound lambda expression consists of the abstraction  $\lambda x. \text{MAN}(x)$  written immediately to the left of the expression  $\text{VINCENT}$ , glued together by @ (we’re using an infix notation for the @-operator). Such concatenations are called *functional applications*; the left-hand expression is called the *functor*, and the right-hand expression the *argument*. Such a concatenation is an instruction to throw away the  $\lambda x.$  prefix of the functor, and to replace every occurrence of  $x$  that was bound by this prefix by the argument. We call this substitution process  *$\beta$ -conversion* (other common names include  *$\beta$ -reduction* and *lambda-conversion*). Performing the  $\beta$ -conversion demanded in the previous example yields:

$\text{MAN}(\text{VINCENT})$ .

Abstraction, functional application, and  $\beta$ -conversion underly much of our subsequent work. The business of specifying semantic representations for lexical items is essentially going to boil down to devising lambda abstractions that specify the missing information, while functional application coupled with  $\beta$ -conversion will be the engine used to combine semantic representations compositionally.

The above example was rather simple, and in one way rather misleading. As our previous experiments have made clear, to deal adequately with noun phrases and determiners (and indeed, many other things) we need to mark more complex kinds of information than that represented by individual variables. We shall use  $\lambda$  for this task as well. For example, our semantic representation of the noun phrase ‘a woman’ will be:

$\lambda Q.\exists x(\text{WOMAN}(x)\wedge Q@x)$ .

Here we are using the variable  $Q$  to indicate that some information is missing (namely, the nuclear scope, to use the linguistic terminology mentioned earlier) and to show where this information has to be plugged in when it is found (it will be the conjoined to  $\text{WOMAN}(x)$ ). We’ll use new variable symbols (typically, capital letters such as  $P$ ,  $Q$ ,  $X$ , and  $Y$ ) for variables which act as place holder for complex information, and we’ll call these new variables *complex variables*.

We are almost ready to examine some linguistic examples, but let’s first clarify one point. The lambda expressions  $\lambda x.\text{MAN}(x)$ ,  $\lambda y.\text{MAN}(y)$ , and  $\lambda z.\text{MAN}(z)$  are equivalent, as are the expressions  $\lambda Q.\exists x(\text{WOMAN}(x)\wedge Q@x)$  and  $\lambda Y.\exists x(\text{WOMAN}(x)\wedge Y@x)$ . All these expressions are functors which when applied to an argument, replace the bound variable by the argument. No matter which argument  $\mathcal{A}$  we choose, the result of applying any of the first three expressions to  $\mathcal{A}$  and then  $\beta$ -converting is  $\text{MAN}(\mathcal{A})$ , and the result of applying either of the last two expressions to  $\mathcal{A}$  is  $\exists x(\text{WOMAN}(x)\wedge \mathcal{A}@x)$ . In short, relabeling bound variables yields lambda expressions which carry out exactly the same glueing task.

The process of relabeling bound variables is called  $\alpha$ -conversion. If a lambda expression  $\mathcal{E}$  can be obtained from a lambda expression  $\mathcal{E}'$  by  $\alpha$ -conversion then we say that  $\mathcal{E}$  and  $\mathcal{E}'$  are  $\alpha$ -equivalent. (Thus  $\lambda x.\text{MAN}(x)$ ,  $\lambda y.\text{MAN}(y)$ , and  $\lambda z.\text{MAN}(z)$  are all  $\alpha$ -equivalent, as are  $\lambda Q.\exists x(\text{WOMAN}(x)\wedge Q@x)$  and  $\lambda Y.\exists x(\text{WOMAN}(x)\wedge Y@x)$ .) In what follows we often treat  $\alpha$ -equivalent expressions as if they were identical. For example, we will sometimes say that the lexical entry for some word is a lambda expression  $\mathcal{E}$ , but when we actually work out some semantic construction, we might use an  $\alpha$ -equivalent expression  $\mathcal{E}'$  instead of  $\mathcal{E}$  itself. As  $\lambda$ -bound variables are merely placeholders for substitution slots, this is clearly sensible. But the reader needs to understand that it’s not merely *permissible* to do this, it can be *vital* to do so if  $\beta$ -conversion is to work as intended.

Suppose that the expression  $\mathcal{F}$  in  $\lambda V.\mathcal{F}$  is a complex expression containing many  $\lambda$  operators. Now, it could happen that when we apply a functor  $\lambda V.\mathcal{F}$  to an argument  $\mathcal{A}$ , some

occurrence of a variable that is free in  $\mathcal{A}$  becomes bound by a lambda operator when we substitute it into  $\mathcal{F}$ . *We don't want this to happen.* Such accidental bindings (as they are usually called) defeat the purpose of working with the lambda calculus. The whole point of developing the lambda calculus was to gain control over the process of performing substitutions. We don't want to lose control by foolishly allowing unintended interactions.

Such interactions need never be a problem. We don't need to use  $\lambda V.\mathcal{F}$  as the functor; any  $\alpha$ -equivalent formula will do. By suitably relabeling the bound variables in  $\lambda V.\mathcal{F}$  we can always obtain an  $\alpha$ -equivalent functor that doesn't bind any of the variables that occur free in  $\mathcal{A}$ , and accidental binding is prevented. Thus, strictly speaking, it is not merely functional application coupled with  $\beta$ -conversion that drives the process of semantic construction in this book, but functional application and  $\beta$ -conversion coupled with (often tacit) use of  $\alpha$ -conversion.

That's all we need to know about the lambda calculus for now—though we will mention that lambda calculus can be introduced from a different, more mathematically oriented, perspective. Now, the mathematical perspective is useful (we discuss it briefly in the Notes at the end of the chapter, and present it in depth in Appendix B) but for all its importance, it is *not* the only legitimate perspective on lambda calculus. The computational perspective we have adopted—lambda calculus as glue language—is equally important, and underpins a great deal of work in computational semantics. So let's save the theoretical work for later, and try putting our new tool to work. Here's a good place to start: does lambda calculus solve the problem we started with? That is, does it get rid of the difficulties we encountered in experiments 1 and 2?

Let's see what's involved in building the semantic representation for 'every boxer walks' using lambdas. The first step is to assign lambda expressions to the different basic syntactic categories. We assign the determiner 'every', the common noun 'boxer', and the intransitive verb 'walks' the following lambda expressions:

'every':  $\lambda P.\lambda Q.\forall x(P@x \rightarrow Q@x)$

'boxer':  $\lambda y.BOXER(y)$

'walks':  $\lambda x.WALK(x)$ .

Before going further, pause a moment. These expressions should remind the reader of something, namely the representations used in experiment 2. For example, in experiment 2 we gave the determiner 'every' the representation

`det(X, Restr, Scope, forall(X, Restr > Scope))`

If we use the Prolog variable `P` instead of `Restr`, and `Q` instead of `Scope` this becomes

$\text{det}(X, P, Q, \text{forall}(X, P \rightarrow Q))$

which is clearly analogous to  $\lambda P. \lambda Q. \forall x (P @ x \rightarrow Q @ x)$ .

But there are also important differences. The experiment 2 representation is a Prolog-specific encoding of missing information. In contrast, lambda expressions are programming language independent (we could work with them in C++ or Lisp, for example). Moreover, experiment 2 “solved” the problem of combining missing information on a rule-by-rule basis. As will soon be clear, functional application and  $\beta$ -conversion provide a completely general solution to this problem.

Let’s return to ‘every boxer walks’. According to our grammar, a determiner and a common noun can combine to form a noun phrase. Our semantic analysis couldn’t be simpler: we will associate the NP node with the functional application that has the determiner representation as functor and the noun representation as argument.

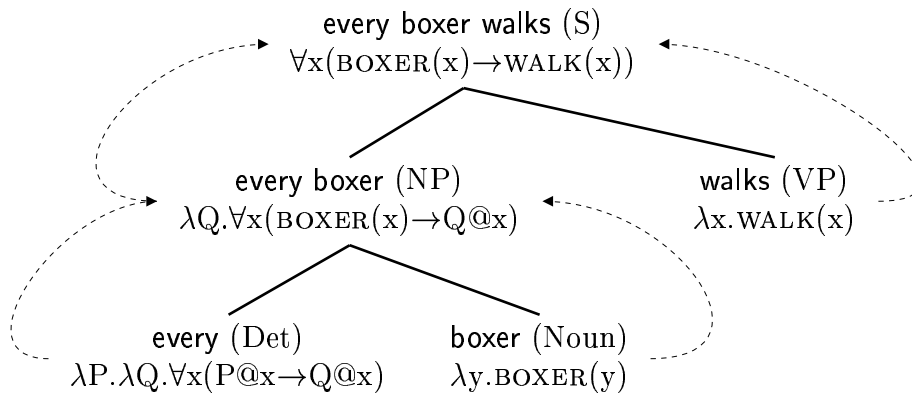

Now, applications are instructions to carry out  $\beta$ -conversion, so let’s do what is required. (Note that as there are no free-occurrences of variables in the argument expression, there is no risk of accidental variable capture, so we don’t need to  $\alpha$ -convert the functor.) Performing the demanded substitution yields:

‘every boxer’:  $\lambda Q. \forall x ((\lambda y. \text{BOXER}(y)) @ x \rightarrow Q @ x)$

But this expression contains a subexpression of the form  $(\lambda y. \text{BOXER}(y)) @ x$ . This is another instruction to perform  $\beta$ -conversion, and when we do so we obtain:

‘every boxer’:  $\lambda Q. \forall x (\text{BOXER}(x) \rightarrow Q @ x)$

We can’t perform any more  $\beta$ -conversions, so let’s carry on with the analysis of the sentence. The following tree shows the final representation we obtain:

Why is the S node associated with  $\forall x(\text{BOXER}(x) \rightarrow \text{WALK}(x))$ ? It's certainly what we want, but where does it come from?

In fact we obtain it by a procedure analogous to that just performed at the NP node. First, we associate the S node with the application that has the NP representation just obtained as functor, and the VP representation as argument:

'every boxer walks':  $(\lambda Q. \forall x(\text{BOXER}(x) \rightarrow Q@x))@(\lambda x. \text{WALK}(x))$ .

Performing  $\beta$ -conversion yields:

'every boxer walks':  $\forall x(\text{BOXER}(x) \rightarrow (\lambda x. \text{WALK}(x))@x)$ .

We can then perform  $\beta$ -conversion on the subexpression  $(\lambda x. \text{WALK}(x))@x$ , and when we do so we obtain the desired representation:

'every boxer walks':  $\forall x(\text{BOXER}(x) \rightarrow \text{WALK}(x))$ .

It is worth reflecting on this example, for it shows that in two important respects semantic construction is getting simpler. First, the process of combining two representations is now uniform: we simply say which of the representations is the functor and which the argument, whereupon combination is carried out by applying functor to argument and  $\beta$ -converting. Second, more of the load of semantic analysis is now carried by the lexicon: it is here that we use the lambda calculus to make the missing information stipulations.

Are there clouds on the horizon? For example, while the semantic representation of a quantifying noun phrase such as 'a woman' can be used as a functor, surely the semantic representation of an NP like 'Vincent' will have to be used as an argument? We avoided this problem in experiment 2 by the variable doubling trick used in the NP rule for proper names—but that was a Prolog specific approach, incompatible with the use of lambda

calculus. Maybe—horrible thought!—we’re going to be forced to duplicate syntactic rules again, just as we did in experiment 1.

In fact, there’s no problem at all. The lambda calculus offers a delightfully simple functorial representation for proper names, as the following examples show:

‘Mia’:  $\lambda P.P@MIA$

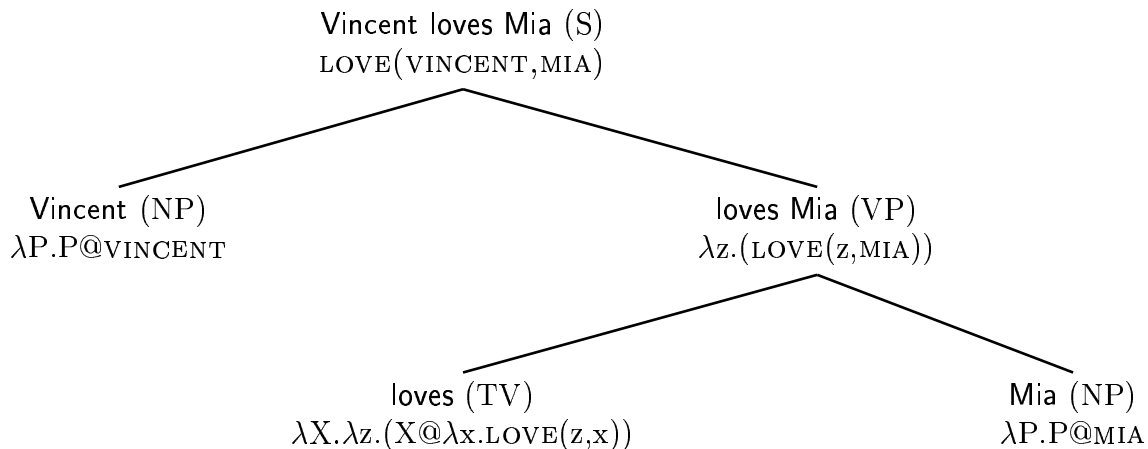

‘Vincent’:  $\lambda P.P@VINCENT$

These representations are abstractions, thus they can be used as functors. However note what such functors do. They are essentially instructions to substitute their argument in  $P$ , which amounts to applying their own arguments to themselves! Because the lambda calculus offers us the means to specify such role-reversing functors, the specter of syntactic rule duplication vanishes.

As an example of these new representations in action, let us build a representation for ‘Vincent loves Mia’. We shall assume that TV semantic representations take their object NP’s semantic representation as argument, so we assign ‘loves’ the following lambda expression:

$\lambda X.\lambda z.(X@ \lambda x.LOVE(z,x)).$

And as in the previous example, the subject NP semantic representation takes the VP semantic representations as argument, so we can build the following tree:

**Exercise 2.3.1** Work through the functional applications and  $\beta$ -conversions required to build the VP and S representations. Make sure you understand the role-reversing idea used in the TV semantic representation.

Let's sum up what we have achieved. Our decision to move beyond the approach of experiment 2 to the more disciplined approach of the lambda calculus was sensible. For a start, we don't need to spend any more time thinking about how to combine two semantic representations—functional application and  $\beta$ -conversion give us a general mechanism for doing so. Moreover, much of the real work is now being done at the lexical level; indeed, even the bothersome problem of finding a decent way of handling NP representations uniformly now has a simple lexical solution.

In fact, for the remainder of this book, the following version of the three tasks listed earlier will underly our approach to semantic construction:

**Task 1** Specify a DCG for the fragment of natural language of interest.

**Task 2** Specify semantic representations for the lexical items with the help of the lambda calculus.

**Task 3** Specify the translation  $\mathcal{R}'$  of a syntactic item  $\mathcal{R}$  whose parts are  $\mathcal{F}$  and  $\mathcal{A}$  with the help of functional application and  $\beta$ -conversion. That is, specify which of the subparts is to be thought of as functor (here it's  $\mathcal{F}$ ), which as argument (here it's  $\mathcal{A}$ ) and then define  $\mathcal{R}'$  to be  $\mathcal{F}'@ \mathcal{A}'$ , where  $\mathcal{F}'$  is the translation of  $\mathcal{F}$  and  $\mathcal{A}'$  is the translation of  $\mathcal{A}$ .

We must now show that the second and third tasks lend themselves naturally to computational implementation.

## 2.4 Implementing Lambda Calculus

Our decision to perform semantic construction with the aid of an abstract glue language (namely, lambda calculus) has pleasant consequences for grammar writing, so we would like to make the key combinatorial mechanisms (functional application and  $\beta$ -conversion), available as black boxes to the grammar writer. From a grammar engineering perspective, this is a sensible thing to do: when writing fragments we should be free to concentrate on linguistic issues.

In this section we build the required black box. In fact we shall build two versions. First we discuss a strikingly simple (but, alas, not fully correct) version which uses unification to simulate  $\beta$ -conversion. Then, simply by redefining one crucial predicate, we convert this to a correct implementation.

## A Unification-Based Implementation

By making ‘clever’ use of Prolog variables, it is almost trivial to implement a black box for performing functional application and  $\beta$ -conversion. And once such a black box is available, we can decorate our little DCG with extremely natural semantic construction code and start building representations. But as the scare quotes indicate, our first implementation of  $\beta$ -conversion is not quite as clever as it seems, and we’ll show where things go wrong and why.

First, we have to decide how to represent lambda expressions in Prolog. Something as simple as the following will do:

```
lambda(L,F)
```

Here *L* is intended to be either a Prolog variable or the Prolog representation of a lambda expression, while *F* is either a first-order formula or the Prolog representation of a lambda expression.

Second, we have to decide how to represent concatenation. Let’s simply transplant our @-notation to Prolog by defining @ as an infix operator:

```
:- op(950,yfx,@).
```

That is, we shall introduce a new Prolog operator @ to explicitly mark where functional application is to take place: the notation *f @ a* will mean apply function *f* to argument *a*. We will build up our representations using these explicit markings, and delay carrying out  $\beta$ -conversion until all the required information is to hand.

Let’s see how to use this notation in DCGs. We’ll deal with the rules first. Actually, there’s practically nothing that needs to be said here. If we work with rules in the manner suggested by (our new version of) task 3, all we need is the following:

```
s(NP@VP)--> np(NP), vp(VP).
```

```
np(PN)--> pn(PN).
```

```
np(Det@Noun)--> det(Det), noun(Noun).
```

```
vp(IV)--> iv(IV).
```

```
vp(TV@NP)--> tv(TV), np(NP).
```

Note that the unary branching rules just percolate up their semantic representation (here coded as Prolog variables NP, VP and so on), while the binary branching rules use @ to build a semantic representations out of their component representations in the manner suggested by task 3. Compared with the code in experiments 1 and 2, this is completely transparent: we simply apply function to argument to get the desired result.

The real work is done at the lexical level. The lexical entries practically write themselves:

```
noun(lambda(X,footmassage(X)))--> [foot,massage].
```

```
noun(lambda(X,woman(X)))--> [woman].
```

```
iv(lambda(X,walk(X)))--> [walks].
```

And here's the code stating that  $\lambda P.P@VINCENT$  is the translation of 'Vincent', and  $\lambda P.P@MIA$  the translation of 'Mia':

```
pn(lambda(P,P@vincent))--> [vincent].
```

```
pn(lambda(P,P@mia))--> [mia].
```

Recall that the lambda expressions for 'every' and 'a' are  $\lambda P.\lambda Q.\forall x.(P@x \rightarrow Q@x)$  and  $\lambda P.\lambda Q.\exists x.(P@x \wedge Q@x)$ . We express these in Prolog as follows.

```
det(lambda(P,lambda(Q,forall(X,(P@X)>(Q@X)))))--> [every].
```

```
det(lambda(P,lambda(Q,exists(X,(P@X)&(Q@X)))))--> [a].
```

Now, this makes semantic construction during parsing extremely easy: we simply use @ to record the required function/argument structure. Here is an example query:

```
?- s(Sem,[mia,snorts],[]).
```

```
Sem = lambda(P,P@mia)@lambda(X,snort(X))
```

But of course, we need to do more work *after* parsing, for we certainly want to reduce these complicated lambda expressions into readable first-order formulas by carrying out  $\beta$ -conversion. The following code does this:

```

betaConvert(Var,Result):-
    var(Var), !, Result=Var.

betaConvert(Functor @ Arg,Result):-
    compound(Functor),
    betaConvert(Functor,ConvertedFunctor),
    apply(ConvertedFunctor,Arg,BetaConverted), !,
    betaConvert(BetaConverted,Result).

betaConvert(Formula,Result):-
    compose(Formula,Functor,Formulas),
    betaConvertList(Formulas,ResultFormulas),
    compose(Result,Functor,ResultFormulas).

```

The first clause of `betaConvert/2` simply records the fact that variables cannot be further reduced (the cut (!) prevents that in this case the other clauses are entered).

The second clause does the most important things: it checks whether the functor is a complex term and, if this is the case, reduces it to a lambda expression (of course it may already be a suitable lambda expression, but it could perfectly well be an application that first had to be reduced). If that succeeds, it applies the converted functor to `Arg` using `apply/3`. The result is reduced as well, as there can be an instruction to convert embedded inside it.

The third and final clause breaks down formulas and predicates and reduces their arguments or subformulas. This is done with the help of:

```

betaConvertList([],[]).
betaConvertList([Formula|Others],[Result|ResultOthers]):-
    betaConvert(Formula,Result),
    betaConvertList(Others,ResultOthers).

```

Now, everything we have done so far is perfectly correct—but we're now going to let ourselves go (temporarily) astray. Only one task remains: we have to define the `apply/3` predicate, which actually carries out the  $\beta$ -conversion. How can we do this? With clever use of Prolog unification we can do so with a single clause:

```

apply(Functor,Argument,Result):-
    Functor=lambda(Argument,Result).

```

The expression `lambda(Argument,Result)` is the functor, the variable `Argument` its argument, and `Result` is the result of the  $\beta$ -conversion. To see why it works, consider the following example. Suppose we wanted to apply  $\lambda x.WALK(x)$  to `VINCENT`. We would do this in Prolog by means of the following query:

```
?- apply(lambda(X,walk(X)),vincent,Result).

X = vincent
Result = walk(vincent)
yes
```

Think about it. The definition of `apply` requires its first argument of the form `lambda(Argument,Result)`, and this is the case. As a result, `Argument` gets unified with `vincent`, and `Result` with `walk(Argument)`, hence `walk(vincent)` as final result. In fact, the definition of `apply/3` can even be slightly simplified to:

```
apply(lambda(Argument,Result),Argument,Result).
```

To finish off, let's define a driver predicate that calls the parser to analyze a sentence, reduces the resulting lambda expression into a first-order formula, and directs the result to the standard output:

```
parse:-
    readLine(Sentence),
    s(LambdaExpression,Sentence,[]),
    betaConvert(LambdaExpression,Formula),
    printRepresentation(Formula).
```

**Exercise 2.4.1** [intermediate] Give the Prolog code for lexical entries of ditransitive verbs such as 'offer' in 'Vincent offers Mia a drink'.

**Exercise 2.4.2** [intermediate] Find a suitable lambda expression for the lexical entry of the determiner 'no', and then give the corresponding Prolog code.

**Exercise 2.4.3** [intermediate] Extend the DCG with a simple treatment of adjectives. Your grammar should be able to assign formulas to expressions like 'A pretty woman likes a tough guy'. Hint: first add the rule for adjectives that combine with nouns to the DCG, then think of how semantic representations for adjectives combine with representations for nouns, and finally implement the lexical entries for adjectives.

**Exercise 2.4.4** [intermediate] Extend the DCG so that it covers negated sentences such as 'Vincent does not walk' or 'It is not the case that Vincent walks'.

**Exercise 2.4.5** [hard] This exercise is about Pereira & Shieber's trick to provide a simple semantics for transitive verbs, i.e., `lambda(X,lambda(Y,love(X,Y)))` for the verb 'love'. The second part of the trick is to change the grammar rule that deals with transitive verbs:

$\text{vp}(\text{lambda}(X, \text{NP@TV})) \rightarrow \text{tv}(\text{lambda}(X, \text{TV})), \text{np}(\text{NP}) .$

Explain why this works and discuss this particular treatment of transitive verbs.

**Exercise 2.4.6** [easy] There is even a way to eliminate the @ instructions and make exclusive use of `lambda/2`! For example, the grammar rule that makes sentences out of noun phrases and verb phrases can be simplified to:

$\text{s}(S) \rightarrow \text{np}(\text{lambda}(\text{VP}, S)), \text{vp}(\text{VP}) .$

Eliminate all @ instructions from the DCG rules given above.

## A Substitution-Based Implementation

Our unification-based implementation of  $\beta$ -conversion (and in particular, the definition `apply/3`) is strikingly simple. Unfortunately it is not fully correct, and it fails for reasons directly relevant to semantic construction. We will go through an example to make the problem clear, and then reimplement `apply/3` properly.

So what's wrong? (It probably not obvious that there's *anything* wrong.) Well, our previous implementation is unable to hand *coordination* correctly. Consider the sentence 'Vincent and Mia dance'. We already know what the lambda expressions are for 'Vincent', 'Mia', and 'dance'. Unsurprisingly, we represent 'and' by the following lambda expression:

(2)  $\lambda X. \lambda Y. \lambda P. (X @ P \wedge Y @ P).$

This is a sensible representation. If we apply it to the representations for 'Mia' and 'Vincent' we get the following result:

(3)  $\lambda P. ((\lambda Q. Q @ \text{VINCENT}) @ P \wedge (\lambda R. R @ \text{MIA}) @ P).$

Applying  $\beta$ -conversion twice yields:

(4)  $\lambda P. (P @ \text{VINCENT} \wedge P @ \text{MIA}).$

That is, one and the same lambda expression  $P$  is to be applied to both `VINCENT` and `MIA`. And this is exactly what we need. In particular, applying this expression to `DANCE` yields the formula `DANCE(VINCENT) ∧ DANCE(MIA)`, which is the representation we would like to have.

So far so good. But now consider what happens when turn this into Prolog. First, the lexical entry for the coordinator 'and' will be as follows:

```
coord(lambda(X,lambda(Y,lambda(P,(X@P) & (Y@P)))))--> [and].
```

Next, assume that we want to analyze ‘Vincent and Mia dance’ and that in the process of combining the lexical entries *X* unifies with the semantic representation of ‘Vincent’, *Y* with the semantic representation of ‘Mia’. Further, assume that *P* gets instantiated with `lambda(X,dance(X))`. Then the two `apply/3` statements, which both use a copy of *P*, try to force the occurrence of *X* to unify with both *mia* and *vincent*. As distinct atoms do not unify, this fails.

**Exercise 2.4.7** Try to cover verb phrase coordination cases like ‘Vincent walks and talks’ in the unification-based approach. Does the unification problem that appears in noun phrase coordination arise here as well? Give an explanation for your observation.

The lesson is clear. Using Prolog unification to simulate  $\beta$ -conversion is a nice idea—but ultimately inadequate. We need to redefine `apply/3` so that it genuinely substitutes the argument expression for all free occurrences in the scope of the lambda expression, and keeps track of the bound and free variables in a formula.

In `comsemLib.pl` there is a version of the Sterling and Shapiro `substitute/4` predicate. This predicate takes a term, a variable, and a formula as its first three arguments, and returns in its fourth argument the result of substituting the term for each free occurrence of the variable in the formula. This is an important predicate (we shall use it again when we implement a first-order theorem prover) so let’s look at the way it’s defined:

```
substitute(Term,Var,Exp,Result):-
    Exp==Var, !, Result=Term.

substitute(_Term,_Var,Exp,Result):-
    \+ compound(Exp), !, Result=Exp.

substitute(Term,Var,Formula,Result):-
    compose(Formula,Functor,[Exp,F]),
    member(Functor,[lambda,forall,exists]), !,
    (
        Exp==Var, !,
        Result=Formula
    );
    substitute(Term,Var,F,R),
    compose(Result,Functor,[Exp,R])
).

substitute(Term,Var,Formula,Result):-
```

```

compose(Formula, Functor, ArgList),
substituteList(Term, Var, ArgList, ResultList),
compose(Result, Functor, ResultList).

```

The `substituteList/4` predicate used in here recursively applies `substitute/4` down the length of the input list to produce the output list:

```

substituteList(_Term, _Var, [], []).

substituteList(Term, Var, [Exp|Others], [Result|ResultOthers]):-
    substitute(Term, Var, Exp, Result),
    substituteList(Term, Var, Others, ResultOthers).

```

Here is an example that the functionality of this predicate.

```

?- substitute(A,B,love(C,B),Result).

Result = love(C,A)

yes

```

This is exactly what we require. We can we redefine `apply/3` as follows:

```

apply(lambda(X,Formula),Argument,Result):-
    substitute(Argument,X,Formula,Result).

```

And that solves the problem.

**Exercise 2.4.8** Check the new grammar rules using  $\beta$ -conversion, especially on cases of noun and verb phrase coordination.

**Exercise 2.4.9** Note that we still use Prolog variables to represent first-order variables, although this is not important for the application predicates as we could use basic atoms instead. Why is it still advantageous? Hint: lexical entries.

**Exercise 2.4.10** In Exercise 2.4.6 we saw how to dispense with `@` in our unification-based implementation. Can we eliminate `@` in the substitution-based implementation?

## 2.5 Grammar Engineering

The explicit notation for functional application and the implementation of  $\beta$ -conversion are the basic tools we shall work with in this book, so it is time to define a bigger grammar and start exploring computational semantics; but let's try to observe some basic principles of grammar engineering as we do so. That is, we should strive for a grammar that is *modular* (each component should have a clear role to play and a clean interface with the other components), *extendible* (it should be straightforward to enrich the grammar should the need arise) and *reusable* (we should be able to reuse a significant portion of the grammar, even when we change the underlying representation language).

Grammar engineering principles have strongly influenced the design of our grammars—and *not*, we would like to stress, purely for pedagogic reasons. We will be experimenting with a wide variety of semantic constructions techniques (for example, in the following chapter we will consider four different techniques for coping with scope ambiguities). Moreover, in Part II we will switch from first-order logic to Discourse Representation Structures as our underlying representation language. As we have learned (often the hard way) incorporating these changes, and keeping track of what is going on, requires a disciplined approach towards grammar design.

We have adopted a fairly simple three-level grammar architecture consisting of a collection of semantically annotated *rules*, a *lexicon*, and a set of *semantic macros*. The rules are DCG rules annotated with an extra slot which applies semantic functions to arguments using the @ operator. The rules given below and their annotations will *not* change in the course of the book; in particular, we will reuse them when we work with Discourse Representation Theory in Part II. The lexicon lists information about words belonging to most syntactic categories in an easily extractable form; again, this component will stay fixed throughout the book. Finally, we have the crucial semantic macros. This is a level at which we state what we have previously called 'lexical entries'. It is here that we will do most of our semantic work, and our modifications will largely be confined to this level.

### The Rules

Here are the core DCG rules that we would *like* to use. These rules license a number of semantically important constructions, such as proper names, determiners, pronouns, relative clauses, the copula construction, and coordination. In addition, the first two rules let us form discourses by stringing together sentences; we'll need these rules in Part II.

d--> s, d.	noun--> noun, coord, noun.
d--> s.	vp--> vp, coord, vp.
s--> np, vp.	vp--> vbar(fin).
np--> np, coord, np.	vp--> mod, vbar(inf).

np--> det, nbar.	vbar(I)--> vbar(I), coord, vbar(I).
np--> pn.	vbar(I)--> tv(I), np.
np--> pro.	vbar(I)--> iv(I).
nbar--> nbar, coord, nbar.	vbar(fin)--> cop, np.
nbar--> noun.	vbar(fin)--> cop, neg, np.
nbar--> noun, pp.	pp--> prep, np.
nbar--> noun, rc.	rc--> relpro, vp.

(Readers unfamiliar with syntax may be wondering what NBAR and VBAR are. Essentially they are a level of phrase structure intermediate between the full phrasal level (NP and VP respectively) and the lexical level (N and V). There is a variety of evidence for the existence of this intermediate level and we refer the reader to any mainstream syntax textbook for further discussion. We introduce this intermediate level because it will be the source of some nice examples in Part II.)

However these are not quite the rules we shall actually use, for the following reason. The coordination rules are left-recursive, hence the standard Prolog DCG interpreter will loop when given this grammar. As we *do* want to give coordination examples, and as we *don't* want to implement a parser that deals with left-recursive rules, we're simply going to adopt the following simple fix which will make a limited form of coordination available to us. We'll add a auxiliary set of categories named **np2**, **np1**, **v2**, **v1**, etc. These auxiliary categories allow us to specify left-recursive rules to a certain depth of recursion. For example, the rules which have something to say about NPs will be replaced by the following:

```

s--> np2, vp2.
np2--> np1.
np2--> np1, coord, np1.
np1--> det, n2.
np1--> pn.
np1--> pro.

```

Similarly, the rules controlling nouns will become:

```

n2--> n1.
n2--> n1, coord, n1.
n1--> noun.
n1--> noun, pp.
n1--> noun, rc.

```

This is a brutal way of dealing with the problem, but it enables us to generate the examples we want without having to worry about left-recursion.

One other shortcoming should be mentioned. We implemented a limited amount of inflectional morphology—all our examples are relentlessly third-person present-tense. This is a shame (tense and its interaction with temporal reference is a particularly rich source of semantic examples), nonetheless, we shall not be short of interesting things to do.

But for all its shortcomings, this small set of rules assigns tree structures to an interesting range of English sentences or small discourses, including:

Mia knows every owner of a hash bar.  
 Vincent or Mia dances.  
 Every boxer that kills a criminal loves a woman.  
 Vincent does not love a boxer or criminal that snorts.  
 She does not love a boxer or criminal that snorts and dances.  
 A boxer snorts. He collapses. Mia is a woman. Vincent is not a boxer.

Let's turn to the semantic annotations. Here the news is extremely pleasant. For a start, the required semantic annotations are utterly straightforward; they are simply the obvious “apply the function to the argument statements” expressed with the help of @. Here, for example, is how we semantically annotate `s --> np2, vp2.`:

`s(NP@VP)--> np2(NP), vp2(VP).`

That is, we simply apply the NP semantics to the VP semantics. None of the rules are much more complex than this. The rules for coordination are the most complex, but even these are straightforward as the following example shows:

`n2((C@N1)@N2)--> n1(N1), coord(C), n1(N2).`

The unary rules, of course, are even simpler for they merely pass the representation up to the mother node. For example:

`np1(NP)--> pn(NP).`

Finally, we've got the lexical rules. These are rules that apply to terminal symbols, the actual strings in the input of the parser, and need to call the lexicon to check if a string belongs to the syntactic category searched for.

`noun(Noun)-->`  
`{`  
`lexicon(noun,Sym,Phrase,_),`  
`nounSem(Sym,Noun)`  
`},`  
`Phrase.`

In this example for nouns, the semantic macro `nounSem` is used to construct the actual semantic representation for a noun. Each lexical category is associated with such a macro, and this enables us to abstract away from specific types of structures. So we have set up the grammar rules in such a way that we are independent from the semantic theory we want to work with, and this is an attractive property as we are going to change the underlying semantic representations in the following chapters.

All these rules will work for us unchanged throughout the book. The reader can find a complete list in the file `englishGrammar.pl`. Furthermore, the file `mainLambda.pl`, that contains the unification- and substitution-based approaches to the lambda calculus of this chapter, already uses these rules in the way described here.

## The Lexicon

Our lexicon lists information about the words belonging to most syntactic categories in a form useful for the interface component that we shall shortly define. The general format of a lexical entry is

```
lexicon(Cat,Sem,Phrase,Misc)
```

where `Cat` is the syntactic category, `Sem` the semantic information introduced by the phrase (normally a relation symbol or a constant, though sometimes we leave this field empty), `Phrase` the string of words that span the phrase, and `Misc` miscellaneous information depending on the type of entry. In particular, `Misc` lists gender information for nouns, pronouns, and proper names (we are going to classify nouns as `male`, `female` or `human`, or `nonhuman`, for this information will be important for pronoun resolution in Part II), and inflectional information for verbs.

Typical entries for intransitive verbs are:

```
lexicon(iv,collapse,[collapses],fin).
lexicon(iv,collapse,[collapse],inf).
lexicon(iv,dance,[dances],fin).
lexicon(iv,dance,[dance],inf).
```

Nouns, on the other hand, are listed in the following format:

```
lexicon(noun,boxer,[boxer],human).
lexicon(noun,bkburger,[big,kahuna,burger],nonhuman).
```

Typical entries for pronouns and determiners are as follows:

```

lexicon(det,_,[every],uni).
lexicon(det,_,[a],indef).

lexicon(pro,_,[he],male).
lexicon(pro,_,[she],female).

```

Note that these entries contain no semantic information. This is because the semantic contribution of pronouns and determiners is not simply a constant or predicate symbol, but rather a relatively complex expression that is dependent on the underlying representation language (quantifiers are dealt with very differently in the DRT based work of Part II, for example). Hence we shall specify the semantics of these categories in the semantic macros.

A small number of important words—in particular, copula and the verb phrase modifier construct ‘does not’, are *not* listed in the lexicon at all. This is because they are not associated with either a relation symbol or a constant and they are not marked for gender, thus their lexicon entry would simply consist of a **Phrase** entry. The semantic macros are the sole source of information about such words.

This way of setting up a lexicon offers natural expansion options. For example, if decided to develop a grammar that dealt with inflectional morphology (which we won’t do so in this book), it is just a matter of extending the general format of entries with one or more fields, and if we did this, it would be natural to list all words in the lexicon.

Refer to `englishLexicon.pl` for a complete listing of the lexicon.

**Exercise 2.5.1** Find out how copula verbs are handled in the lexicon and grammar, and how the semantic representation for sentences like ‘Mia is a boxer’ and ‘Mia is not Vincent’ are generated.

## The Semantic Macros

We now come to the most important part of the grammar, the lexicon/rules interface. Essentially, this component is where we state what we called semantic macros in the text. As the introduction of `apply/3` and `conjoin/3` has reduced the process of combining semantic representations to an elegant triviality, and as the only semantic information the lexicon supplies is the relevant constant and relation symbols, the interface is where the real semantic work will be done. Let’s consider some examples of semantic macros right away.

```

nounSem(Sym,lambda(X,Formula)):-
    compose(Formula,Sym,[X]).

pnSem(Sym,lambda(P,P@Sym)).

```

```
tvSem(Sym,lambda(K,lambda(Y,K@lambda(X,Formula)))):-
  compose(Formula,Sym,[Y,X]).
```

The first macro, `nounSem/2`, builds a semantic representation for any noun given the predicate symbol `Sym`, turning this into a formula lambda abstracted with respect to a single variable (for example `lambda(X,Formula)`). The representation is built using `compose/3` to incorporate it into the required lambda expression. The semantic macro for proper names (`pnSem/2`) is even simpler, and the one for transitive verbs (`tvSem/2`) is similar to that of the macro for nouns, apart from handling two variables rather than just one.

As we've already mentioned, the interface also contains self-contained entries for the determiners. Here they are:

```
detSem(uni,lambda(P1,lambda(P2,forall(X,(P1@X) > (P2@X))))).
```

```
detSem(indef,lambda(P1,lambda(P2,exists(X,(P1@X) & (P2@X))))).
```

These, of course, are just the old-style 'lexical entries' we are used to.

From now on, we will always use the lexicon and (with the exceptions of a few pedagogic explorations of other formats) the rules listed above too. To put it another way: *from now on the primary locus of change will be the semantic macros*. For example, it is here that we will develop treatments of quantifier scope, pronoun resolution, presupposition accommodation, and VP-ellipsis. For a complete listing of the macros we have just been discussing, see `semMacrosLambda.pl` (page 222), but we shall see many more types of semantic macros as we work our way through the book.

## Software Summary of Chapter 2

`experiment1.pl` The code of our first experiment in semantic construction for a small fragment of English. (page 216)

`experiment2.pl` The second experiment in semantic construction. (page 218)

`mainLambda.pl` The main file for the implementation of the lambda calculus. Consults all necessary files and contains the driver for the parser. You can either choose to make use of the (simple but incorrect) unification-based implementation of application, or use the substitution based approach. (page 220)

`betaConversion.pl` The predicates that implement  $\beta$ -conversion. (page 221)

`semMacrosLambda.pl` The semantic macros for the lambda calculus. (page 222)

`englishLexicon.pl` Our standard English lexical entries. Contains entries for nouns, proper names, intransitive and transitive verbs, prepositions, and pronouns. (page 202)

`englishGrammar.pl` Our standard grammatical rules for a fragment of English. Rules cover basic sentences, noun phrases, relative clauses and modification of prepositional phrases, verb phrases, and a limited form of coordination. (page 207)

## Notes

Compositionality is a simple and natural idea—and one capable of arousing an enormous amount of passion and controversy. Traditionally attributed to Gottlob Frege (the formulation “the meaning of the whole is a function of the meaning of its parts” is often called Frege’s principle) it received a precise mathematical formulation in the late 1960s. For detailed and accessible overview of the compositionality concept, the reader should consult Janssen 1997.

The idea of using the simply typed lambda calculus to specify the meanings of lexical entries, and using functional application as the basic mechanism for combining representations, is due to Richard Montague. Indeed, what we have presented in this chapter is simply a computational perspective on a very small part of Montague semantics.

Montague's original papers are well worth reading (they are collected in Thomason 1974) nonetheless they are dense and most readers will be better off approaching Montague semantics via either Dowty, Wall and Peters (1981) or volume 2 of Gamut (1991b). Both contain good, careful, textbook level expositions of Montague's key ideas. A more demanding (and correspondingly more rewarding) exposition is due to Janssen (see Janssen 1986a and Janssen 1986b). These are well worth reading, but rather hard to get hold of. If you see them, grab them. For a good overview of Montague's work, and an account of the major directions in which his work has been developed, Partee 1997 is a must. This account is rich in historic detail, and is an excellent starting point for deeper forays into the semantic literature.

The mathematical and logical literature on the lambda calculus is huge. Here are some of the more obvious points of entry. The bible of untyped lambda calculus is Barendregt 1984. Barendregt 1991 is a good starting point for material on typed systems. However these are very technical accounts, perhaps best suited for occasional reference. For a more approachable account of both typed and untyped systems, try Hindley and Seldin 1986. Turner 1997 is fairly technical, but usefully broad, and notes applications in linguistics and computer science. Finally, for logical work on the systems Montague himself used, and a number of interesting variants, Gallin 1975 is indispensable.

The references given so far approach lambda calculus and its applications in natural language semantics from a logical perspective. In this book we have tried to emphasize that there is a very natural computational perspective too. Not only is the lambda calculus a useful tool for gluing representations together, but the basic idea emerges, with seeming inevitability, when one sits down and actually tries to do semantic construction in Prolog—or at least, that is what we have tried to suggest by approaching lambda calculus via experiments 1 and 2. We hasten to add that this 'seeming inevitability' is clear only with the benefit of hindsight. The links between the ideas of logic programming and Montague semantics seem to have first been explicitly drawn in Pereira and Shieber 1987.

Lambda calculus is probably the mostly widely used tool for semantic construction, and it is the tool of choice in this book—nonetheless, it is *not* the only tool available. Indeed, it has a most interesting rival: the use of *feature structures* and *feature structure unification*. The reader who wants to go further in computational semantics really should be acquainted with this approach. Gazdar and Mellish 1989 contains a good text book level introduction to its use in building syntactic and semantic representations, and indeed, on its uses in pragmatics too. Another readable paper on the topic is Moore 1989. This paper compares the approach with the use of lambda calculus. More recently, linear logic has been proposed as a suitable glue language for semantic construction; see Dalrymple et al. 1997.

Refer to classical DCG-grammar with semantic construction (Pereira?).

# Chapter 3

## Underspecified Representations

This chapter develops methods for dealing with an important semantic phenomenon: *scope ambiguities*. Sentences with scope ambiguities are often semantically ambiguous (that is, they have at least two non-equivalent first-order representations) but fail to exhibit any syntactic ambiguity. As our approach to semantic construction is firmly based on the idea of using syntactic structure to guide semantic construction, we face an obvious problem here: if there is no syntactic ambiguity, we will only be able to build one of the possible representations. As scope ambiguities are very common, we need to develop ways of coping with them right away.

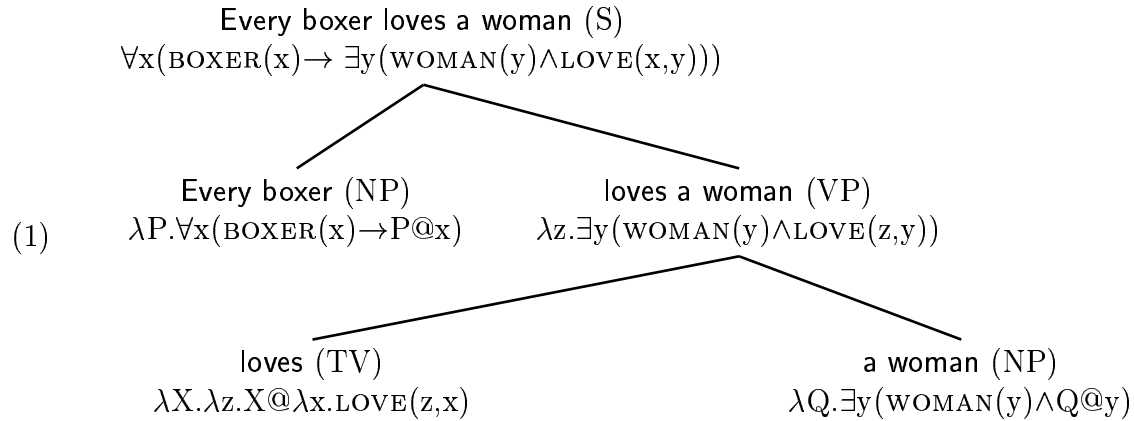

We are going to investigate and implement four different approaches to scope ambiguities: Montague’s original method, two storage based methods, and finally a more recent approach based on the idea of *underspecified representations*. Each approach is interesting in its own right, and the underspecification-based approach we shall eventually describe is a powerful tool that we shall use throughout the book. But as well as developing practical solutions to a pressing problem, this chapter also tells an important story. Computational semanticists are adopting an increasingly abstract perspective on what representations are and how they should be built. Once we have studied the evolutionary line leading from Montague’s method to contemporary underspecification-based methods, we will be in a better position to appreciate why.

### 3.1 Scope Ambiguities

Scope ambiguity is a common phenomenon and can arise from a wide variety of sources. In this chapter we will mostly be concerned with *quantifier scope ambiguities*. These are ambiguities that arise in sentences containing more than one quantifying noun phrase; for example, ‘Every boxer loves a woman’.

Now, the methods of the previous chapter allow us to assign a representation to this

sentences as follows:

The first-order formula we have constructed states that for each boxer there is a woman that he loves; there might be different women for different boxers. However, ‘Every boxer loves a woman’ has a second meaning (or to use the linguistic terminology, a second *reading*) that is captured by the following formula:

$$(2) \quad \exists y(\text{WOMAN}(y) \wedge \forall x(\text{BOXER}(x) \rightarrow \text{LOVE}(x,y)))$$

This says that there is one woman who is loved by all boxers.

It is clear that these readings are somehow systematically related, and that this relation has something to do with the relative scopes of the quantifiers: both first-order representations have the same components, but somehow the parts contributed by the two quantifying noun phrases have been shuffled around. In the first representation the existential quantifier contributed by ‘a woman’ has ended up inside the scope of the universal quantifier contributed by ‘every boxer’ and in the second representation the nesting is reversed. In fact it is usual to say that in the first reading ‘every boxer’ *has scope over* (or *outscores*) ‘a woman’, while in reading (2) it is the other way around.

Unfortunately, these scoping possibilities are not reflected syntactically: the only plausible parse tree for this sentence is the one just shown. Thus while it makes good semantic sense to say that in reading (2) ‘a woman’ outscopes ‘every boxer’, we can’t point to any syntactic structure that would explain why this scoping possibility exists. As each word in the sentence is associated with a fixed lambda expression, and as semantic construction is simply functional application guided by the parse tree, this means there is no way for us to produce this second reading. This difficulty clearly strikes at the very heart of our semantic construction methodology. Moreover, scope ambiguities are extremely common, so we urgently need a solution.

In this chapter we examine in detail four increasingly sophisticated (and increasingly abstract) approaches to the problem. The first of these, Montague’s original method, introduces some important ideas, but as it relies on the use of additional rules it isn’t compatible with the approach to grammar engineering adopted in this book. However by introducing a more abstract form of representation—the *store*—we will be able to capture Montague’s key ideas. Stores were introduced by Robin Cooper and are arguably the earliest example of *underspecified representations*. Nonetheless, stores are relatively concrete. By simultaneously moving to more abstract underspecified representations, and replacing the essentially generative perspective underlying storage methods with a constraint based perspective, we arrive at *hole semantics*, the underspecified representation we shall use in this book. This will enable us to handle quantifier scope ambiguities, and the scope ambiguities created by constructs such as negation, in a uniform way.

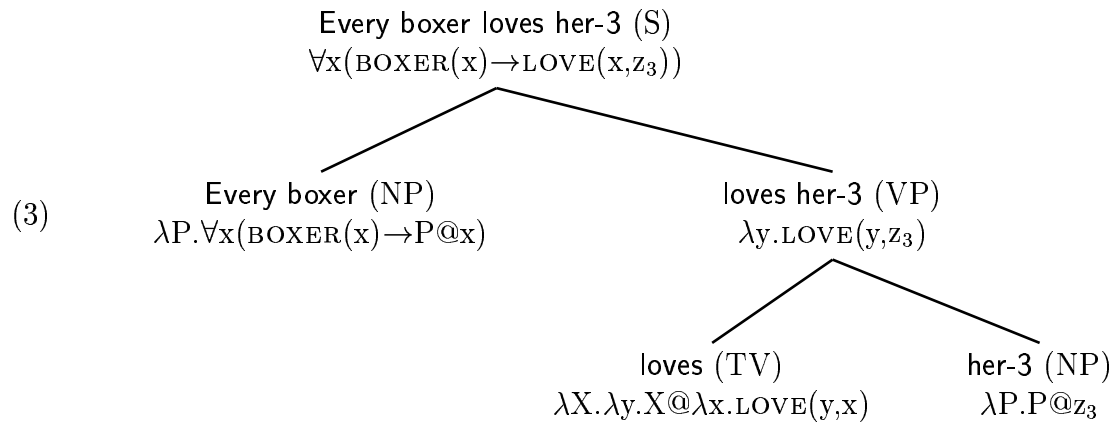

**Exercise 3.1.1** Some readers may be wondering whether scope ambiguities really are a genuine problem at all. Consider ‘Every boxer loves a woman’. In a sense, representation (1) is sufficient to cover both readings of our example, since it is entailed by the other reading (2). Arguably, that makes the stronger representation superfluous: perhaps it is pragmatically inferred from the weaker one with the help of contextual knowledge. So do we really need techniques for coping with quantifier ambiguity?

We do, as we want the reader to demonstrate here. First, find examples of quantifier scope ambiguities that give rise to logically *independent* readings (that is, neither implies the other). Secondly, find an example where direct construction doesn’t lead to the weakest reading (that is, the reading entailed by the others). Feel free to use determiners such as ‘one’, ‘many’ and ‘most’ to construct your examples.

## 3.2 Montague’s Approach

Montague semantics makes use of the direct method of constructing semantic representations for quantified NPs studied in the previous chapter. However, motivated in part by quantifier scope ambiguities, Montague also introduced a rule of quantification (often called *quantifier raising*) that allowed a more indirect approach. The syntactic idea involved is very simple. Instead of directly combining syntactic entities with the quantifying noun phrase we are interested in, we are permitted to choose an ‘indexed pronoun’ and to combine the syntactic entity with the indexed pronoun instead. Intuitively, such indexed pronouns are ‘placeholders’ for the quantifying noun phrase. When this placeholder has moved high enough in the tree to give us the scoping we are interested in, we are permitted to replace it by the quantifying NP of interest.

As an example, let’s consider how to analyze ‘Every boxer loves a woman’. Here’s the first part of the tree we need:

Instead of combining ‘loves’ with the quantifying term ‘a woman’ we have combined it with the placeholder pronoun ‘her-3’. This pronoun bears an ‘index’, namely the numeral ‘3’. The placeholder pronoun is associated with a ‘semantic placeholder’, namely  $\lambda P. P@z_3$ . As we shall see, it is the semantic placeholder that does most of the real work for us. Note that the pronoun’s index appears as subscript on the free variable in the semantic placeholder. From a semantic perspective, choosing an indexed pronoun really amounts to opting to work with the semantic placeholder (instead of the semantics of the quantifying NP) and stipulating which free variable the semantic placeholder should contain.

Now, the key point the reader should note about this tree is how *ordinary* it is. True, it contains a weird looking pronoun ‘her-3’—but, that aside, it’s just the sort of structure we’re used to. For a start, the various elements are syntactically combined in the expected way. Moreover semantic construction is also being performed completely standardly: the placeholder pronoun has the semantics  $\lambda P. P@z_3$ —which is the standard pronoun semantics—and (as the reader should check) the representations for ‘loves her-3’ and ‘every boxer loves her-3’ are constructed using functional application just as we discussed in the previous chapter. In short, we have ‘raised’ both the syntactic and semantic placeholders high into the tree, and we have done so in a completely orthodox way.

Now for the next step. We want to ensure that ‘a woman’ outscopes ‘every boxer’. By using the placeholder pronoun ‘her-3’, we have delayed introducing ‘a woman’ into the tree. But ‘every boxer’ is now firmly in place, so if we replaced ‘her-3’ by ‘a woman’ we would have the desired scoping relation. Predictably, there is a rule that lets us do this: given a quantifying NP, and a sentence containing a placeholder pronoun, we are allowed to construct a new sentence by substituting the quantifying NP for the placeholder. In short, we are allowed to extend the previous tree as follows:

But what's happening semantically? We know what formula we want to be assigned to the top S node (namely, the formula 2) but how can we ensure it gets there? Let's think the matter through.

We want 'a woman' to take wide scope over 'every boxer' semantically. Hence we should use the semantic representation associated with 'a woman' as the function. (To see this, simply look at the form of its semantic representation. When we apply it to an argument and lambda convert, we will be left with an existentially quantified expression, which is what we want.) But what should its argument be? There is only one reasonable choice. It must be the representation associated with 'every boxer loves her-3' lambda abstracted with respect to  $z_3$ :

(5)  $\lambda z_3.\forall x(\text{BOXER}(x)\rightarrow\text{LOVE}(x,z_3))$

Why is this? Well, right at the bottom of the tree we made use of the semantic placeholder  $\lambda P.P@z_3$ . When we raised this placeholder up the tree using functional application, we were essentially 'recording' what the semantic representation of 'a woman' would have encountered if we had used it directly. (Remember, we did nothing unusual, either syntactically or semantically, during the raising process.) The formula  $\forall x(\text{BOXER}(x)\rightarrow\text{LOVE}(x,z_3))$  is the record of these encounters. When we are ready to 'play back' this recorded information, we lambda abstract with respect to  $z_3$  (thus indicating that this variable is the crucial one, the one originally chosen) and feed the resulting expression as an argument to the semantic representation of 'a woman'. Lambda conversion will glue this record into its rightful place, and, as the following tree shows, everything will work out just right:

That's it. Summing up, Montague's approach makes use of syntactic and semantic placeholders so that we can place quantifying NPs in parse trees at exactly the level required to obtain the desired scope relations. A neat piece of 'lambda programming' (we call it

Montague's trick) ensures that the semantic information recorded by the placeholder is re-introduced into the semantic representation correctly.

Enough theory; can we write a Prolog program which integrates the previous chapter's work on lambda-based semantic construction with quantifier raising? Up to a point, we can. Unfortunately, most of the work is going to have to take place in our DCG rules, and the result is not particularly attractive from a grammar engineering perspective. Still, let's go through it systematically; it's interesting, and we shall be able to re-use some ideas and notation in our later work on storage.

We first add a new grammar rule for noun phrases that introduces the semantic representation of a pronoun (that is, we add a 'placeholder rule'). The pronoun will be associated with an index, and this index, together with the ordinary semantic representation of the noun phrase, will be passed to the mother node of the syntactic tree. (We do this by making use of additional arguments to the DCG rules.)

The following DCG rule implements these ideas. `Det@Noun` is the semantics of the quantifying noun phrase, constructed in the usual way. The term `lambda(P,P@I)`, where `I` is the index, mimics the usual pronoun semantics (it's our semantic placeholder). The first argument of `np1` holds the list of raised quantifiers, together with their associated indexes. We call these elements *indexed binding operators*, and represent them as two-place terms of the form `bo(Sem,Index)`.

```
np1([bo(Det@Noun,I)],lambda(P,P@I))--> det(Det), n2(Noun).
```

Note that we have used a Prolog list to store the indexed binding operators. This is because it makes it easy to introduce more indexes (if we have to) and straightforward to check whether any indexes were introduced at all.

The other clauses for noun phrases are essentially the ones we had in our original implementation, but we have to add an additional argument (namely, an empty list) to make them compatible with our new rule for quantifier raising.

```
np1([],Det@Noun)--> det(Det), n2(Noun).
```

```
np1([],NP)--> pn(NP).
```

```
np1([],NP)--> pro(NP).
```

Needless to say, the other rules in our grammar fragment need to be rewritten to take our extension into account. First we consider verb phrases. Intransitive verbs don't combine with NPs, so we simply give them the empty list as additional argument. Transitive verbs must pass on the list of raised quantifiers (coded as `Q`) that they get from the noun phrase:

```
v1([],I,V)--> iv(I,V).
```

```
v1(Q,I,TV@NP)--> tv(I,TV), np2(Q,NP).
```

We need to be able to replace the placeholder pronouns by the real quantifiers. This happens at the sentential level, thus we need a rule saying that a sentence can be constructed out of sentence with a raised quantifier, by abstracting over the index, and applying the semantics of the raised quantifier to the resulting expression.

```
s([],NP@lambda(I,S))--> s([bo(NP,I)],S).
```

The standard rule for forming sentences remains unchanged, save we need (yet again) to add an extra argument and pass through the raised quantifiers.

```
s(Q,NP@VP)--> np2([],NP), vp2(Q,VP).
```

It is time to test our program (`mainMontague.pl`), using the `parse/0` predicate:

```
?- parse.
```

```
> Every boxer loves a woman.
```

```
Readings:
```

```
1 exists(A,woman(A)&forall(B,boxer(B)>love(B,A)))
```

```
2 forall(A,boxer(A)>exists(B,woman(B)&love(A,B)))
```

```
yes
```

```
?-
```

It gives us exactly the two readings that we want.

What can we say about Montague's approach? It seems fair to say that while the idea of using semantic placeholders regulated by Montague's trick is natural, the quantifier raising mechanism used to exploit these ideas isn't very appealing. For a start, we are placing a heavy burden on the grammar rules. In principal, grammar rules are there to tell us about syntactic structure—but now we're being forced to write additional rules that say something about scope ambiguity. Moreover, as will be apparent to readers who worked through our Prolog code, the obvious implementation simply isn't very attractive. All that fiddling about with extra arguments—and just to cope with sentences containing a transitive verb and two quantifying noun phrases in subject and object position! Extending the program to deal with a wide range of scope ambiguity inducing constructions would not be pleasant. So let us abandon quantifier raising, and turn instead to *storage methods*.

**Exercise 3.2.1** Extend the quantifier raising analysis to ditransitive verbs, and check how many readings it gives for sentences like ‘A boxer gives every woman a foot massage’. Are these the readings you would expect?

**Exercise 3.2.2** [hard] The file `englishGrammarMontague.pl` contains the revised DCG rules for Montague quantifier raising analysis. The rules for constructing complex noun phrases (such as ‘a man that told every joke’) don’t deal with raising yet. Repair this.

## 3.3 Storage Methods

Storage methods are an elegant way of coping with quantifier scope ambiguities: they neatly decouple scope considerations from syntactic issues, making it unnecessary to add new grammar rules. Moreover, both historically and pedagogically, they are the natural approach to explore next, for they draw on the key ideas of Montague’s approach (in essence, they exploit semantic placeholders and Montague’s trick in a computationally more natural way) and at the same time they anticipate key themes of modern underspecification-based methods.

### Cooper Storage

Cooper storage is a technique developed by Robin Cooper for handling quantifier scope ambiguities. In contrast to the work of the previous section, semantic representations are built directly, without adding to the basic grammar rules. The key idea is to associate each node of a parse tree with a *store*, which contains a ‘core’ semantic representation together with the quantifiers associated with nodes lower in the tree. After the sentence is parsed, the store is used to generate scoped representations. The order in which the stored quantifiers are retrieved from the store and combined with the core representation determines the different scope assignments.

To put it another way, instead of simply associating nodes in parse trees with a single lambda expression (as we have done until now), we are going to associate them with a core semantic representation, together with the information required to turn this core into the kinds of representation we are familiar with. Viewed from this perspective, stores are simply a more abstract form of semantic representation—representations which encode, compactly and without commitment, the various scope possibilities; in short, they are a simple form of underspecified representation.

Let’s make these ideas precise. Formally, a store is an  $n$ -place sequence. We represent stores using the angle brackets  $\langle$  and  $\rangle$ . The first item of the sequence is the core semantic representation; it’s simply a lambda expression. (Incidentally, if we wanted to, we could insist that we’ve been using stores all along: we need merely say that when we previously

talked of assigning a lambda expression  $\phi$  to a node, we *really* meant that we assigned the 1-place store  $\langle \phi \rangle$  to a node.) Subsequent elements (if any) are pairs  $(\beta, i)$ , where  $\beta$  is the semantic representation of an NP (that is, another lambda expression) and  $i$  is an index. An index is simply a label which picks out a free variable in the core semantic representation. As we shall see, this index has the same purpose as the indexes we used for Montague-style raised quantifiers. We call pairs  $(\beta, i)$  *indexed binding operators*.

How do we use stores for semantic construction? Unsurprisingly, the story starts with the quantified noun phrases (that is, noun phrases formed with the help of a determiner). Instead of simply passing on the store assigned to them, quantified noun phrases are free to ‘re-package’ the information it contains before doing so. (Other sorts of NPs, such as proper names, aren’t allowed to do this.) More precisely, quantified noun phrases are free to make use of the following rule:

### Storage (Cooper)

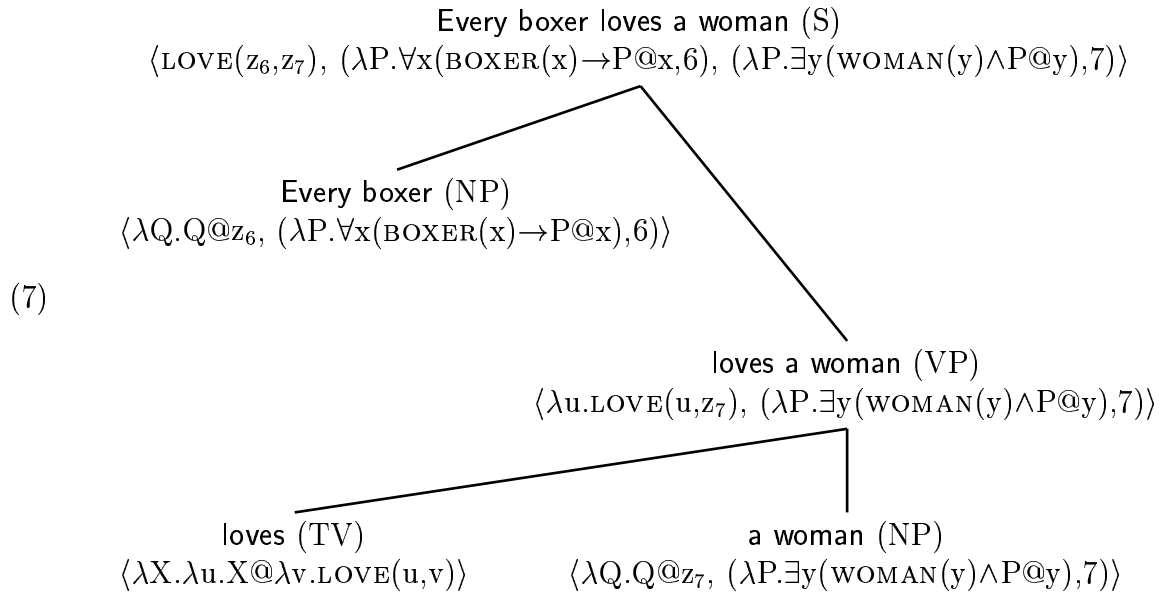

If the store  $\langle \phi, (\beta, j), \dots, (\beta', k) \rangle$  is a semantic representation for a quantified NP, then the store  $\langle \lambda P.P@z_i.(\phi, i), (\beta, j), \dots, (\beta', k) \rangle$ , where  $i$  is some unique index, is also a representation for that NP.

The crucial thing to note is that the index associated with  $\phi$  is identical with the subscript on the free variable in  $\lambda P.P@z_i$ . (After all, if we decide to store  $\phi$  away for later use, it’s sensible to keep track of what its argument is.)

In short, from now on when we encounter a quantified NP we will be faced by a choice. We can either pass on  $\phi$  (together with any previously stored information) straight on up the tree, or we can decide to use  $\lambda P.P@z_i$  as the core representation, store the quantifier  $\phi$  on ice for later use (first taking care to record which variable it is associated with) and pass on this new package. The reader should be experiencing a certain feeling of *deja vu*. We’re essentially using the pronoun representation  $\lambda P.P@z_i$  as a semantic placeholder, just as we did in the previous section. Indeed, as will presently become clear, our shiny new storage technology re-uses the key ideas of quantifier storage in a fairly direct way.

Incidentally, the storage rule is *not* recursive. It offers a simple two way choice: either pass on the ordinary representation (that is, the store  $\langle \phi, (\beta, j), \dots, (\beta', k) \rangle$ ) or use the storage rule to form  $\langle \lambda P.P@z_i.(\phi, i), (\beta, j), \dots, (\beta', k) \rangle$  and pass this new store on up instead. We’re *not* offered—and we don’t want or need—the option of reapplying the storage rule to this new store to form  $\langle \lambda P.P@z_m.(\lambda P.P@z_i.(\phi, i), (\beta, j), \dots, (\beta', k)), (\phi, i), (\beta, j), \dots, (\beta', k) \rangle$ . Intuitively, we’re offered a straight choice between keeping the lambda expression associated with the quantified NP in the active part of the memory (that is, in the first slot of the store) or placing it, suitably indexed, in the freezer for later consumption.

It’s time for an example. Let’s analyze ‘Every boxer loves a woman’ using Cooper storage. Here’s (part of) the relevant tree.

Note that the nodes for ‘a woman’ and ‘Every boxer’ are both associated with 2-place stores. Why is this? Consider the node for ‘a woman’. We know from our previous work that the lambda expression associated with ‘a woman’ is  $\lambda P. \exists y (\text{WOMAN}(y) \wedge P@y)$ . In our new representations-are-stores world view, this means that the 1-place store

$$\langle \lambda P. \exists y (\text{WOMAN}(y) \wedge P@y) \rangle$$

is a legitimate interpretation for the NP ‘a woman’. But remember—this is not our only option. We are free to use the storage rule, and this is what we did when building the above tree. We’ve picked a brand new free variable (namely  $z_7$ ), used the placeholder  $\lambda Q. Q@z_7$  as the first item in the store, and ‘iced’  $\lambda P. \exists y (\text{WOMAN}(y) \wedge P@y)$ , first recording the fact that  $z_7$  is the variable relevant to this expression. Essentially the same story could be told for the NP ‘every boxer’, save that there we chose the new free variable  $z_6$ .

Once this has been grasped, the rest is easy. In particular, if a functor node  $\mathcal{F}$  is associated with a store  $\langle \mathcal{F}', (\beta, j), \dots, (\beta', k) \rangle$  and its argument node  $\mathcal{A}$  is associated with the store  $\langle \mathcal{A}', (\beta'', l), \dots, (\beta''', m) \rangle$ , then store associated with the node  $\mathcal{R}$  whose parts are  $\mathcal{F}$  and  $\mathcal{A}$  is

$$\langle \mathcal{F}'@ \mathcal{A}', (\beta, j), \dots, (\beta', k), (\beta'', l), \dots, (\beta''', m) \rangle.$$

That is, the first slot of the store really is the active part: it’s where the core representation is built. If you examine the above tree, you’ll see that the stores associated with ‘loves a woman’ and ‘every boxer loves a woman’ were formed using this ‘functional application in the first slot’ method. Note that in both cases we’ve simplified  $\mathcal{F}'@ \mathcal{A}'$  using lambda conversion.

But we’re not yet finished. We now have a sentence, and this sentence is associated with an abstract unscoped representation (that is, a store), but of course, at the end of the day

we really want to get our hands on some ordinary scoped first-order representations. How do we do this?

This is the task of *retrieval*, a rule which is applied to the stores associated with sentences. Retrieval removes one of the indexed binding operators from the freezer, and combines it with the core representation to form a new core representation. (If the freezer is empty, then the store associated with the S node must already be a 1-place sequence, and thus we already have the expression we are looking for.) It continues to do this until it has used up all the indexed binding operators. The last core representation obtained in this way will be the desired scoped semantic representation (we hope!).

What does the combination process involve? Suppose retrieval has removed a binding operator indexed by  $i$ . It lambda abstracts the core semantic representation with respect to the variable bearing the subscript  $i$ , and then functionally applies the newly retrieved binding operator to the newly lambda-abstracted-over core representation. The result is the new core representation, and it replaces the old core representation as the first item in the store. More precisely:

### Retrieval (Cooper)

Let  $\sigma_1$  and  $\sigma_2$  be (possibly empty) sequences of binding operators. If the store  $\langle \phi, \sigma_1, (\beta, i), \sigma_2 \rangle$  is associated with an expression of category S, then the store  $\langle \beta @ \lambda z_i. \phi, \sigma_1, \sigma_2 \rangle$  is also associated with this expression.

Hey—we’re simply performing Montague’s trick with the aid of stores!

Let’s return to our example and apply the retrieval rule to the store associated with the S node. Now, this store contains two indexed binding operators. The retrieval rule allows us to remove either of them and to combine it with the core representation. Suppose we choose to first retrieve the quantifier for ‘every boxer’ (that is, the indexed binding operator in the second slot of the store). Then the retrieval rule tells us that the following store must be associated with the S node:

$$(8) \quad \langle \lambda P. \forall x (\text{BOXER}(x) \rightarrow P @ x) @ \lambda z_6. \text{LOVE}(z_6, z_7), (\lambda P. \exists y (\text{WOMAN}(y) \wedge P @ y), 7) \rangle$$

Using lambda conversion, this simplifies to:

$$(9) \quad \langle \forall x (\text{BOXER}(x) \rightarrow \text{LOVE}(x, z_7)), (\lambda P. \exists y (\text{WOMAN}(y) \wedge P @ y), 7) \rangle$$

No more lambda conversions are possible, but there’s still a quantifier left in store. Retrieving it produces:

$$(10) \quad \langle \lambda P. \exists y (\text{WOMAN}(y) \wedge P @ y) @ \lambda z_7. \forall x (\text{BOXER}(x) \rightarrow \text{LOVE}(x, z_7)) \rangle$$

The result is the reading where ‘a woman’ outscopes ‘every boxer’, as becomes clear if we perform two more lambda conversions to obtain:

$$(11) \langle \exists y(\text{WOMAN}(y) \wedge \forall x(\text{BOXER}(x) \rightarrow \text{LOVE}(x, y))) \rangle$$

How do we get the other reading? We simply retrieve the quantifiers in the other order. We suggest that the reader attempts the following exercise immediately.

**Exercise 3.3.1** Show the steps involved in applying retrieval that yield the reading where ‘every boxer’ has scope over ‘a woman’.

Let’s now implement Cooper storage in Prolog.

The first steps are pretty obvious: we’ll represent stores as lists, and indexed binding operators as terms of the form `bo(Quant, Index)`, just as we did in the previous section. Thus the following Prolog list represents a store:

```
[walk(X), bo(lambda(lambda(Y, F), forall(Y, boxer(Y) > F)), X)]
```

But now we need to think a little. The semantic representations we want to work with are stores, not just plain lambda expressions. Moreover, we want to reuse our lexicon and rules, and the idea of combining representations with the `@` operator is hard-wired into our rules. But we have said nothing about combining stores using `@`: do we face a problem here? No: it’s fairly obvious that we simply need to ‘lift’ our use of `@` so that we can meaningfully talk of combining stores with stores—and indeed, stores with quantifiers—using `@`. As stores are just lists of lambda expressions and binding operators, this shouldn’t be too difficult to do. But one matter deserves to be stressed: *the results of these ‘lifted’ uses of @ should always be stores*. This will guarantee that the sentence ends up being associated with a store, and hence that store-retrieval can proceed as explained above. Let’s define a predicate `buildStore/2` that carries out these combinations for us:

```
buildStore(quant(Quant) @ Store, NewStore) :-
    buildStore(Store, [Arg|S]),
    npStorage(Quant, [Arg|S], NewStore).

buildStore(Store1 @ Store2, [F@A|S]) :-
    buildStore(Store1, [F|S1]),
    buildStore(Store2, [A|S2]),
    append(S1, S2, S).

buildStore([Sem|Store], [Sem|Store]).
```

This predicate has three clauses. Now, the second clause simply combines two stores using @ in the obvious way (it makes use of the familiar fact that the first slot of the store really is where the core representation is built) and the result is clearly a new store. The third clause ends the recursion. So far so good—but what about the first clause, which lets us combine a quantifier and a store using @?

To understand what is going on here, let's examine the predicate `npStorage/3` that the first clause uses:

```
npStorage(Quant,[Arg|Store],[lambda(P,P@X),bo(Quant@Arg,X)|Store]).
```

That is, this predicate simply stores the quantifier in the expected way. But then it is clear that the first clause of `buildStore/2` simply says that combining a quantifier and a store using @ simply amounts to storing that quantifier—thus once again, our extended notion of functional application yields a new store.

Two other remarks should to be made. First, storage should be a possibility *only* available to quantified noun phrases, and this explains the presence of the marker `quant/1`. This marker (or feature) signals that the representation we have in our hands is of a genuine quantifier. Second, note that this version of `buildStore/2` makes storage *compulsory* for quantifiers, not *optional*. This turns out not to be a good idea, and we shall eventually modify our definition of `buildStore/2` accordingly—but more on that topic later.

With `buildStore/2` at our disposal, it now makes sense to talk of combining stores using @, and moreover we know that the result will always be a new store. So we are ready to define the semantic macros. Here's the one for a universal determiner:

```
detSem(uni,quant(lambda(P,lambda(Q,forall(X,(P@X)>(Q@X)))))).
```

Apart from the `quant`-marker, there is nothing really new in this entry—indeed it looks exactly like our previous semantic macros. As for the other categories, the only change we make is that the representations we work with are stores, as the following macros show:

```
tvSem(Sym,[lambda(K,lambda(Y,K@lambda(X,Formula)))):-  
  compose(Formula,Sym,[Y,X]).
```

```
pnSem(Sym,[lambda(P,P@Sym)]).
```

Thus we have all that we need to create stores: all that remains is to implement retrieval.

The Prolog predicate that copes with retrieval is `sRetrieval/2`. Its first argument is the store, its second argument the derived scoped representation. If the store contains just one element, then this is the scoped formula; the first clause deals with this case.

Otherwise, it takes an element from the store using the predicate `removeFromStore/3`, lambda abstracts `Sem` (the first item in the list) with respect to the retrieved variable, and applies the retrieved quantifier to it, yielding a new semantic representation that will be  $\beta$ -converted later. Note that the `sRetrieval` predicate is recursive, thus it will eventually reduce the store to a list containing just one item, namely a scoped representation.

```
sRetrieval([S],S).
sRetrieval([Sem|Store],S):-
    removeFromStore(bo(Q,X),Store,NewStore),
    sRetrieval([Q@lambda(X,Sem)|NewStore],S).
```

But why does this generate *all* the possible scoped representations? In fact, we obtain all the possible readings thanks to `removeFromStore/3`. This predicate is defined in such a way that, if there is more than one element in the store, it succeeds when it removes *any* element at all from it. Therefore, `sRetrieval` produces (via the Prolog backtracking mechanism) all the scoped representation possible.

```
removeFromStore(X,[X|T],T).
removeFromStore(X,[Y|T],[Y|R]):-
    removeFromStore(X,T,R).
```

The driver is transparent: we use `buildStore` to build a store, `sRetrieval` to generate the various representations, and then the familiar  $\beta$ -conversion predicate to simplify:

```
parse:-
    readLine(Sentence),
    s(Sem,Sentence,[]),
    setof(Result,Store^Retrieved^(buildStore(Sem,Store),
                                   sRetrieval(Store,Retrieved),
                                   betaConvert(Retrieved,Result)),
          SemSet),
    printReadings(SemSet).
```

Again, it is time to test our program:

```
?- parse.

> Every boxer loves a woman.

Readings:
1 exists(A,woman(A)&forall(B,boxer(B)>love(B,A)))
2 forall(A,boxer(A)>exists(B,woman(B)&love(A,B)))
```

Unsurprisingly, these are exactly the results we want.

Summing up, Cooper storage is a generalization of Montague’s rule of quantification that makes use of abstract representations called stores. From the perspective of computational semantics, it has a distinct advantage over Montague’s approach: we don’t need to make use of additional grammar rules. Indeed, when you get down to it, all we really needed to do to implement Cooper storage was to define what it meant to combine our new representations using `@` (this is what `buildStore/2` did for us) and then provide two additional predicates, `npStorage` and `sRetrieval`, which gave us the ability to manipulate our new representations in ways that plain old functional application couldn’t. Cooper storage is indeed a natural and useful technique.

**Exercise 3.3.2** How many scoped representations are retrieved for ‘every piercing that is done with a needle is okay’? (Take ‘is done with’ as a two place relation, and view ‘is okay’ as a one place predicate.) Are they all correct?

**Exercise 3.3.3** What does the store (before retrieval) for ‘every piercing is done with a needle’ look like? And after retrieval?

**Exercise 3.3.4** In the original discussion of Cooper storage the storage of quantifiers was an *optional* alternative to functional application. In our implementation, all quantified NPs were forced to use storage. Why is there no difference between the two strategies for the given fragment of grammar. Can you think of natural language examples where it actually does differ?

## Keller Storage

Cooper storage allows us a great deal of freedom in retrieving information from the store. We are allowed to retrieve quantifiers in any order we like, and the only safety net provided is the use of co-indexed variables and Montague’s trick.

Is this really safe? We haven’t spotted any problems so far—but then we’ve only discussed one kind of scope ambiguity, namely those in sentences containing a transitive verb with quantifying NPs in subject and object position. However there are lots of other syntactic constructions that give rise to quantifier scope ambiguities, for instance relative clauses (12) and prepositional phrases in complex noun phrases (13):

(12) Every piercing that is done with a gun goes against the entire idea behind it.

(13) Mia knows every owner of a hash bar.

Both examples give rise to scope ambiguities. For example, in (13) there is a reading where Mia knows all owners of (possibly different) hash bars, and a reading where Mia knows

all owners that own one and the same hash bar. Moreover, both examples contain nested NPs. In the first example ‘a gun’ is a sub-NP of ‘every piercing that is done with a gun’, while in the second, ‘a hash bar’ is a sub-NP of ‘every owner of a hash bar’.

We’ve never had to deal with nested NPs before. Is Cooper storage delicate enough to cope with them, and does it allow us to generate all possible readings? Let’s examine example (13) more closely and find out. This is the store:

$$\langle \text{KNOW}(\text{MIA}, z_2), (\lambda P. \forall y (\text{OWNER}(y) \wedge \text{OF}(y, z_1) \rightarrow P @ y), 2), (\lambda Q. \exists x (\text{HASHBAR}(x) \wedge Q @ x), 1) \rangle$$

**Exercise 3.3.5** Verify this.

There are two ways to perform retrieval: by pulling the universal quantifier off the store before the existential, or vice versa. Let’s explore the first possibility. Pulling the universal quantifier off the store yields (after lambda conversion):

$$(14) \quad \langle \forall y (\text{OWNER}(y) \wedge \text{OF}(y, z_1) \rightarrow \text{KNOW}(\text{MIA}, y)), (\lambda Q. \exists x (\text{HASHBAR}(x) \wedge Q @ x), 1) \rangle$$

Retrieving the existential quantifier then yields (again, after lambda conversion):

$$(15) \quad \langle \exists x (\text{HASHBAR}(x) \wedge \forall y (\text{OWNER}(y) \wedge \text{OF}(y, x) \rightarrow \text{KNOW}(\text{MIA}, y))) \rangle$$

This states that there is a hash bar of which Mia knows every owner. This is one of the readings we would like to have. So let’s explore the other option. If we pull the existential quantifier from the S store first we obtain:

$$(16) \quad \langle \exists x (\text{HASHBAR}(x) \wedge \text{KNOW}(\text{MIA}, z_2)), (\lambda P. \forall y (\text{OWNER}(y) \wedge \text{OF}(y, z_1) \rightarrow P @ y), 2) \rangle$$

Pulling the remaining quantifier off the store then yields:

$$(17) \quad \langle \forall y (\text{OWNER}(y) \wedge \text{OF}(y, z_1) \rightarrow \exists x (\text{HASHBAR}(x) \wedge \text{KNOW}(\text{MIA}, y))) \rangle$$

But this is not at all we wanted! Cooper storage has given us not a sentence, but a formula containing the free variable  $z_1$ . What is going wrong?

Essentially, the Cooper storage mechanism is ignoring the hierarchical structure of the NPs. The sub-NP ‘a hash bar’ contributes the free variable  $z_1$ . However, this free variable does not stay in the core representation: when the NP ‘every owner of a hash bar’ is processed, the variable  $z_1$  is moved out of the core representation and put on ice. Hence lambda abstracting the core representation with respect to  $z_1$  *isn’t* guaranteed to take into account

the contribution that  $z_1$  makes—for  $z_1$  makes its contribution indirectly, via the stored universal quantifier. Everything is fine if we retrieve this quantifier first (since this has the effect of ‘restoring’  $z_1$  to the core representation) but if we use the other retrieval option it all goes horribly askew. Cooper storage doesn’t impose enough discipline on storage and retrieval, thus when it has to deal with nested NPs, it over-generates.

What are we to do? An easy solution would be to build a ‘free variable check’ into the retrieval process. That is, we might insist that we can only retrieve an indexed binding operator if the variable matching the index occurs in the core representation.

But this isn’t very principled; it deals with the symptoms, not the cause. The heart of the problem is that Cooper storage rides roughshod over the hierarchical structure of NPs; we should try to deal with this head on. (Incidentally, arguably there’s also an empirical problem: the free variable solution isn’t adequate if one extends the grammar somewhat. We won’t discuss this here but refer the reader to the Notes.)

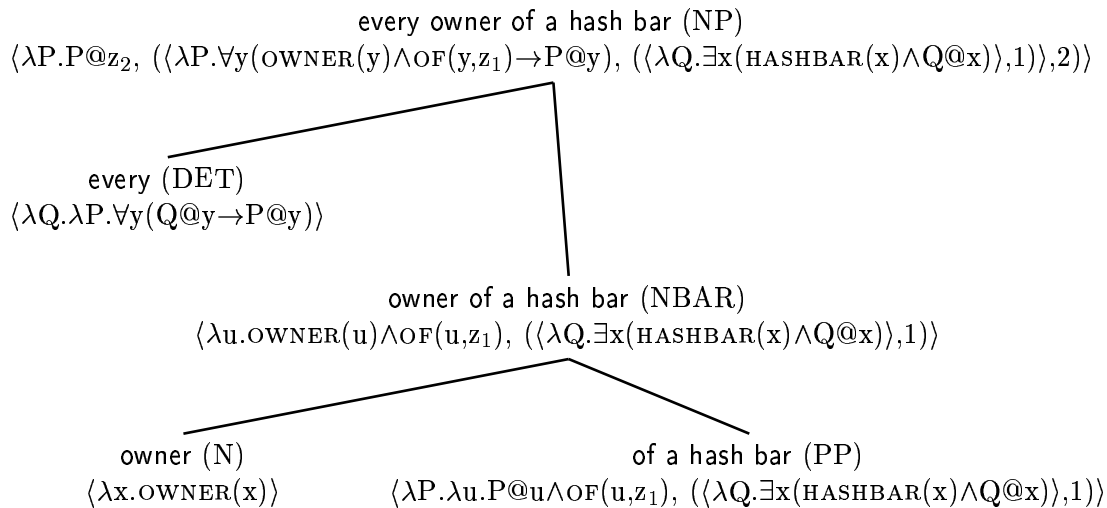

Here’s an elegant solution due to Bill Keller: allow nested stores. That is, allow stores to contain other stores. Intuitively, the nesting structure of the stores should automatically track the nesting structure of NPs in the appropriate way. As an added bonus, nesting is easier to implement than a free variable check.

Here’s the new storage rule:

### Storage (Keller)

If the (nested) store  $\langle \phi, \sigma \rangle$  is an interpretation for an NP, then the (nested) store  $\langle \lambda P.P@z_i, (\langle \phi, \sigma \rangle, i) \rangle$ , for some unique index  $i$ , is also an interpretation for this NP.

To see how this new storage rule works, consider how we assemble the representation associated with the complex noun phrase ‘every owner of a hash bar’.

As for the retrieval rule, it will now look like this.

### Retrieval (Keller)

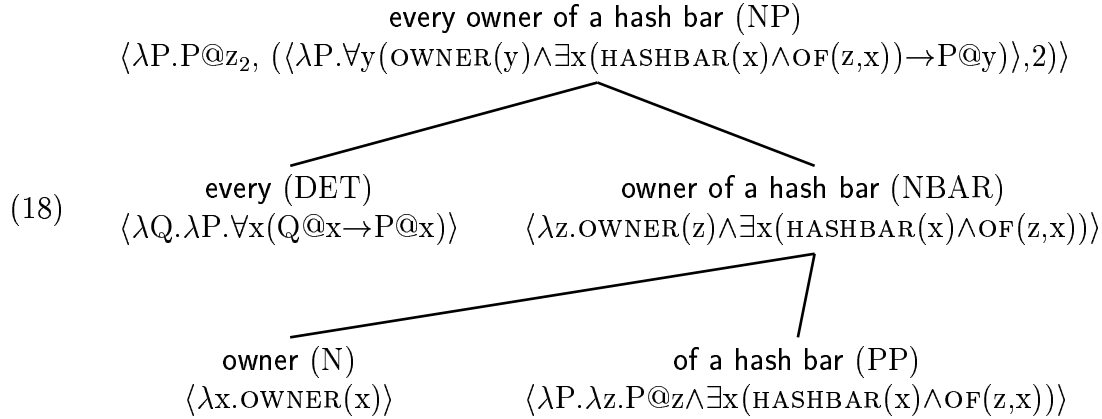

Let  $\sigma$ ,  $\sigma_1$  and  $\sigma_2$  be (possibly empty) sequences of binding operators. If the (nested) store  $\langle \phi, \sigma_1, (\langle \beta, \sigma \rangle, i), \sigma_2 \rangle$  is an interpretation for an expression of category S, then  $\langle \beta @ \lambda z_i. \phi, \sigma_1, \sigma, \sigma_2 \rangle$  is too.

The new retrieval rule ensures that any operators stored while processing  $\beta$  become accessible for retrieval only after  $\beta$  itself has been retrieved. Nesting automatically overcomes the problem of generating readings with free variables. To see how it works in practice, let's return to our original example. The nested store associated with 'Mia knows every owner of a hash bar' is

$$\langle \text{KNOW}(\text{MIA}, z_2), (\langle \lambda P. \forall y (\text{OWNER}(y) \wedge \text{OF}(y, z_1) \rightarrow P @ y), (\langle \lambda Q. \exists x (\text{HASHBAR}(x) \wedge Q @ x), 1 \rangle), 2) \rangle$$

There is only one way to perform retrieval: first pulling of the universal quantifier, followed by the existential quantifier, resulting in (15). Since this is the only possibility, the unwanted reading (17) is not generated.

But wait a minute: how do we get the reading where Mia knows all owners of possible different hash bars? In fact, this couldn't be easier. All we have to do is avoid storing the sub-NP 'a hash bar'. If we do this, we can produce the following tree:

This leads to the following analysis for 'Mia knows every owner of a hash bar':

$$(19) \langle \text{KNOW}(\text{MIA}, z_2), (\langle \lambda P. \forall y (\text{OWNER}(y) \wedge \exists x (\text{HASHBAR}(x) \wedge \text{OF}(y, x)) \rightarrow P @ y), 2) \rangle$$

There is only one operator the store. Retrieving it yields the reading we want.

(20)  $\langle \forall y(\text{OWNER}(y) \wedge \exists x(\text{HASHBAR}(x) \wedge \text{OF}(y,x)) \rightarrow \text{KNOW}(\text{MIA},y)) \rangle$

So our earlier Prolog implementation of Cooper storage—which made storage compulsory—really was linguistically naive. While making storage compulsory didn’t have any malign effects in the previous section, this was only because we were working with a very restricted grammar fragment. As the previous example shows, as soon as we move to a richer fragments in which nested NPs are possible, storage really does need to be optional to ensure that all possible readings are generated.

A few rather trivial changes are all that’s needed to turn our Cooper storage program into a Keller storage program. Here’s the new version of `npStorage/3` we need. It’s identical to the previous version, save for the third argument, which now treats stores as lists of lists:

```
npStorage(Quant, [Arg|Store], [lambda(P,P@X), bo([Quant@Arg|Store], X)]).
```

The only other change is in the first clause of `removeFromStore/3`, to enable it to deal with lists of lists:

```
removeFromStore(bo(O,I), [bo([O|T1], I) | T2], T) :-
    append(T1, T2, T).
```

```
removeFromStore(X, [Y|T], [Y|R]) :-
    removeFromStore(X, T, R).
```

And that’s it. The over-generation problem is solved. We’ll never see unwanted free variables again.

The last thing to do is thinking of a way to incorporate the optionality of the storage rule into the Prolog program. Naturally, we will implement this by making use of the following disjunctive rule.

```
buildStore(quant(Quant) @ Store, NewStore) :-
    buildStore(Store, [Arg|S]),
    (
        NewStore = [Quant@Arg|S]
    ;
        npStorage(Quant, [Arg|S], NewStore)
    ).
```

Let’s test our program (we’ll use the `parse/0` predicate of the Cooper implementation) and see what happens:

?- parse.

> Mia knows every owner of a hash bar.

Readings:

```
1 exists(A,hashbar(A)&forall(B,of(B,A)&owner(B)>know(mia,B)))
2 forall(A,exists(B,hashbar(B)&of(A,B)&owner(A)>know(mia,A)))
```

Let's sum up what we have learned. First, the original version of Cooper storage doesn't handle storage and retrieval in a sufficiently disciplined way, and this causes it to generate spurious readings (in fact, nonsensical readings) when faced with nested NPs. The problem can be elegantly cured by making use of nested stores, and implementing this idea requires only trivial changes to our earlier Prolog code. Second, storage really must be optional. If we are to generate all the required readings in examples involving nested NPs, we must be free not to store the NPs encountered low down in the hierarchy. If these changes are made, we have a flexible tool for handling quantifier scope ambiguities.

**Exercise 3.3.6** Give the PL translations for the five readings of 'a man likes every woman with a five-dollar shake'. You might have noticed that the number of correct readings for this example is less than the combinatorial possibilities of the quantifiers that are involved. Naively, one would expect to have  $3! = 6$  readings for this example. Why is one reading excluded? Try similar examples on the program.

Nonetheless, storage methods have their limitations. For a start, they are not as expressive as we might wish: although Keller storage predicts the five readings for

(21) One criminal knows every owner of a hash bar

it doesn't allow us to insist that 'every owner' must out-scope 'a hash bar', while at the same time leaving the scope relation between subject and object noun phrase unspecified. To put it another way, storage is essentially a technique which enables us to represent all possible meanings compactly; it doesn't allow us to express additional *constraints* on possible readings, and this is precisely what most modern underspecified representations let us do.

Moreover, storage is a technique specifically designed to handle *quantifier* scope ambiguities. Unfortunately, many other constructs (for example, negation) also give rise to scope ambiguities, and storage has nothing to say about these. Consider the sentence 'Vincent doesn't clean every car'. This has a reading where for each car it is not the case that Vincent cleans it; and a second, possibly preferred, reading where there are some cars (but not all) that Vincent doesn't clean. We would like an uniform approach to scope ambiguity, not a separate mechanism for each construct—and this as another motive for turning to the more abstract view offered by current work on underspecification.

## 3.4 Underspecification

There has been a great deal of recent interest in the use of *underspecified representations* to cope with scope ambiguities; so much so that it often seems as if semantics has entered an age of underspecification. With the benefit of hindsight, however, we can see that the idea of underspecified representations isn't really new. In our work on storage, for example, we associated stores, not simply lambda expressions, with parse tree nodes; and as we have already remarked, a store is in essence an underspecified representation. What *is* new is both the sophistication of the new generation of underspecified representations (as we shall see, they offer us a great deal of flexibility and expressive power), and, more importantly, the way such representations are now regarded by semanticists.

In the past, storage style (and other 'funny') representations seem to have been regarded with some unease. They were certainly a useful tool, but they appeared to live in a conceptual no-man's-land—not really semantic representations, but not syntax either—that was hard to classify. The key insight that underlies current approaches to underspecification is that it is both *fruitful* and *principled* to view representations more abstractly. That is, it is becoming increasingly clear that the level of representations is richly structured, that doing semantic construction elegantly demands deeper insight into this structure, and that—far from being a sign of some fall from semantic grace—semanticists should learn to play with representations in more refined ways.

In this book, we shall explore an approach to underspecification called *hole semantics*. We have chosen hole semantics because it is the approach we are most familiar with (the method is due to Johan Bos), it illustrates many of the key ideas of current approaches to underspecification in an elegant and simple way, and we will be able to use it when we switch to working with Discourse Representation Structures. Other approaches to underspecification are noted in the Notes at the end of the chapter.

### Hole Semantics

Viewed from a distance, hole semantics shares a very obvious similarity with storage methods: at the end of the parsing stage, sentences *won't* be associated with a semantic representation. Rather, they will be associated with abstract representations from which the desired representation can be read off. Viewed closer up, however, it is clear that hole semantics adopts a far more radical perspective on representations than storage does.

Hole semantics is essentially a constraint-based approach to semantic representation. That is, at the end of the parsing process the method delivers a set of *constraints*: any first-order representation which fulfills these constraints—which govern how the various bits and pieces produced during the parsing process can be plugged together—is a permissible semantic representation for the sentence. This contrasts sharply to the essentially generative approach offered by storage (*Here's the store! Enumerate the readings like this!*) and

the source of much of the method's power.

Exactly what kinds constraints can we state? Answering this question is a two-step process.

1. We first need to *unplug* our underlying representation formalism (here, first-order logic) by permitting formulas to be built which contain *holes* (essentially variables over missing structure).
2. Then, with the help of such unplugged formulas, we can define a simple constraint language which governs the way semantic representations are *plugged together*.

(That is, we first break the underlying representation language down into convenient chunks, and then we define a simple constraint language governing how these chunks can be assembled into bigger units. The resulting representations we call underspecified semantic representations, USRs for short.)

Let's take care of the first-step right away. We'll now define what we mean by a PLU formula (this stands for *Predicate Logic Unplugged*). In Part II of the book we'll unplug the language of Discourse Representation Structures in a similar way.

Suppose we have chosen some vocabulary. (We'll assume that the vocabulary is function free; this is purely for simplicity and has no bearing on the work that follows.) We must then chose a countably infinite set  $H$  of holes. This is simply any convenient set of new symbols (that is, symbols distinct from those used to build the first-order formulas) which we will usually write as  $h_0, h_1, h_2, h_3, \dots$ , and so on. The hole  $h_0$  will play a special role in the work that follows—it's used to state constraints, but it *won't* be used in PLU formulas. So let's give a name to the set containing just the ordinary holes (that is  $h_1, h_2, h_3, \dots$ , and so on) for these are the ones that are relevant at this stage. We'll use  $H^+$  to denote this set and call it the set of *internal holes*. Note that  $H = \{h_0\} \cup H^+$ .

Now, what are the PLU-terms over this signature and  $H^+$ ? Simply the ordinary first-order terms over this signature: the holes don't play any role at this level. That is, the terms we have at our disposal are simply the constants and variables.

Next, what are the *atomic PLU-formulas*? Again, simply the familiar ones; the holes don't play any role here either:

If  $R$  is a relation symbol of arity  $n$ , and  $t_1, \dots, t_n$  are terms, then  $R(t_1, \dots, t_n)$  is a PLU-formula.

Now we are ready for the definition of PLU-formulas:

1. All atomic PLU formulas are PLU formulas.
2. If  $h$  is an internal hole, then  $h$  is a PLU formula.

3. If  $\phi$  and  $\psi$  are PLU formulas, then  $\neg\phi$ ,  $(\phi \rightarrow \psi)$ ,  $(\psi \vee \phi)$ ,  $(\psi \wedge \phi)$  are PLU formulas.
4. If  $x$  is a variable, and  $\phi$  is a PLU formula, then  $\forall x\phi$  and  $\exists x\phi$  are PLU formulas.
5. Nothing else is a PLU formula.

This completes the first stage in the definition of our constraint language. Let's turn to the second step. Our USRs (underspecified semantic representations) will be built using PLU-formulas, a special new symbol  $\leq$ , and a set of new symbols called *labels* which we will write as  $l_1, l_2, l_3, \dots$ , and so on. What kind of USRs can we form? Here's an example. As we have already mentioned, sentences are going to be associated with a USR. Here's the USR associated with 'Every boxer loves a woman':

$$(22) \quad < \left\{ \begin{array}{c} l_1 \\ l_2 \\ l_3 \\ h_0 \\ h_1 \\ h_2 \end{array} \right\}, \left\{ \begin{array}{l} l_1 : \forall x(\text{BOXER}(x) \rightarrow h_1) \\ l_2 : \exists y(\text{WOMAN}(y) \wedge h_2) \\ l_3 : \text{LOVE}(x, y) \end{array} \right\}, \left\{ \begin{array}{c} l_1 \leq h_0 \\ l_2 \leq h_0 \\ l_3 \leq h_1 \\ l_3 \leq h_2 \end{array} \right\} >$$

Everything the reader needs to know about constraints can be gleaned from this example. USRs have three components. The left hand side is a set of labels and holes used in the USR. The middle component consists of a set of PLU-formulas preceded by a label. The right hand side consists of a set of constraints of the form  $l \leq h$ , where  $l$  is a label and  $h$  is a hole. Note that the special hole  $h_0$  occurs in the right-hand component of the USR.

But what does this USR mean? Essentially it tells us how we are permitted to plug together the labeled formulas to build a first-order formula. The special hole  $h_0$  is a variable that stands for the first-order formula that we will eventually build. This formula will be built by plugging together three labeled PLU-formulas given in the middle component of the USR. Plugging together simply means substituting one of these 3 PLU formulas in another. (Incidentally, when we carry out such a substitution we only substitute the PLU formula, not its label as well. The label is simply an identifier that enables us to state the right hand side constraints succinctly). Any plugging will do—as long as it satisfies the constraints given on the right hand side. These constraints are essentially constraints on *subformulas*, and are best thought of visually. Each arrow in the following diagram corresponds to a  $\leq$  expression in an obvious way:

The constraints are set up in such a way that the basic PLU formula  $\text{LOVE}(x,y)$  is forced to be out-scoped by the consequent of the universal quantifier's scope, and the second conjunct of the existential quantifier's scope.

Now it's time to say a little more about *resolving* these ambiguous representations. The holes underspecify scope, and in order to give us non-ambiguous interpretations, each hole should be *plugged* with a formula in such a way that all the constraints are satisfied. In other words, we should be sure that each hole gets associated with some label. Obviously, no label can be plugged into two different holes at the same time. Therefore, a so-called *plugging* is a one-to-one correspondence from holes to labels (i.e., a bijective function, with the set of holes as domain and the set of labels as codomain). A plugging for a proper USR is admissible if the instantiations of the holes with labels result in a representation in which there is no contradiction spelled out by the constraints.

There are two pluggings, as is easy to verify:

	$h_0$	$h_1$	$h_2$
$P_1$	$l_1$	$l_2$	$l_3$
$P_2$	$l_2$	$l_3$	$l_1$

Plugging  $P_1$  interprets (22) as giving the universal quantifier wide scope, out-scoping the existential quantifier. The corresponding formula in predicate logic is (23), which is true in a model where all boxers love a woman, but not necessarily the same woman.

$$(23) \quad \forall x (\text{BOXER}(x) \rightarrow \exists y (\text{WOMAN}(y) \wedge \text{LOVE}(x,y)))$$

Plugging  $P_2$  interprets (22) as the existential quantifier out-scoping the universal quantifier. In a model where there is some woman that is loved by all boxers, this interpretation denotes truth. A corresponding formula in predicate logic is (24).

$$(24) \quad \exists y (\text{WOMAN}(y) \wedge \forall x (\text{BOXER}(x) \rightarrow \text{LOVE}(x,y)))$$

## The Plugging Algorithm

Before turning to the plugging algorithm we have to consider the design of Prolog representations for our PLU-formulas. Labels and holes are represented as Prolog variables (as with first-order variables, this gives us the practical advantage that any introduction of a label or hole appears as a new occurrence). With this we are able to represent PLU formulas. Further, we have `leq(L,H)` as the Prolog notation for the constraint  $L \leq H$ . And finally, labeled formulas are formed by putting together a label with a formula using the Prolog inbuilt `:` operator.

A USR itself is represented as `usr(D,L,C)`, where *D* is the set of labels and holes (the *Domain*), *L* a list of labeled formulas, and *C* a list of constraints. Here is a sample representation:

```
usr([L1,L2,L3,H0,H1,H2],
    [L1:exists(X,H1&H2),L2:boxer(X),L3:collapse(Y)],
    [leq(L1,H0),leq(L2,H1),leq(L3,H2),leq(L3,H0)])
```

This Prolog term is our representation in PLU for ‘A boxer collapses’. We won’t provide predicates to check for properness of USRs—instead we supply a plugging algorithm straightaway and assume that the USRs we work with are connected, have a unique top, and are acyclic.

The heart of the plugging algorithm is centered around `plugHole/4`. Its first argument is the hole to be plugged (normally we start with the top hole of the USR, and work recursively through the representation until we’ve plugged all holes). The second argument are the labeled formulas (coded as a difference list—used to keep track of which labeled formulas are left for plugging and which are not), and the third argument is the list of constraints imposed by the USR. Its last argument *Scope* is a list of formulas that, under the current reading, outscope *Formula*.

```
plugHole(Formula,LFs1-LFs3,Constraints,Scoped):-
    select(Label:Formula,LFs1,LFs2),
    checkConstraints(Label,Constraints,[Formula|Scoped]),
    variablesInTerm(Formula,[],-Arguments),
    checkArguments(Arguments,LFs2-LFs3,Constraints,[Formula|Scoped]).
```

With `select/3` (see `comsemPredicates.pl`) we pick a labeled formula to be plugged and remove it from the list. This predicate is backtrackable—so if it turns out that we picked one that violates the constraints we can pick another instead later. We add *Formula* to the list of scoped formulas and check if no constraints are violated.

Then we continue plugging, by identifying the arguments of the newly plugged formula with `variablesInTerm/2`. This predicate, defined in the library file `comsemPredicates.pl`,

takes a term and returns all its variables. The rest of the work is done with the help of `checkArguments/4`. It traverses through the list of arguments, and according to the type of argument (recall that these can be holes, labels, or ordinary first-order variables), continues the plugging process.

The first clause of `checkArguments/4` takes care of holes. We identify holes by imposing a member-check on the constraints. Next this hole is plugged using `plugHole/4`, and the remaining arguments are checked.

```
checkArguments([Arg|Rest], LFs1-LFs3, Constraints, Scoped) :-
    member(leq(_, Hole), Constraints),
    Hole == Arg, !,
    plugHole(Hole, LFs1-LFs2, Constraints, Scoped),
    checkArguments(Rest, LFs2-LFs3, Constraints, Scoped).
```

Clause 2 cares about labels. In that case the corresponding labeled condition is removed from the list of labeled formulas and its arguments are checked as there might be holes among them.

```
checkArguments([Arg|Rest], LFs1-LFs4, Constraints, Scoped) :-
    select(Label:Formula, LFs1, LFs2),
    Label == Arg, !,
    Formula = Arg,
    variablesInTerm(Formula, [] - Arguments),
    checkArguments(Arguments, LFs2-LFs3, Constraints, Scoped),
    checkArguments(Rest, LFs3-LFs4, Constraints, Scoped).
```

The third clause carries on the recursion if the argument is neither a hole nor a label, hence a first-order variable, which we don't need to bother about (note that the two clauses above use the cut preventing to enter this third clause).

```
checkArguments([_|Rest], LFs1-LFs2, Constraints, Scoped) :-
    checkArguments(Rest, LFs1-LFs2, Constraints, Scoped).
```

Finally, there is a clause that ends the recursion:

```
checkArguments([], LFs-LFs, _, _).
```

A typical Prolog call to start the algorithm is `?- plugHole(Top, LFs-[], Cons, [])`, where `Top` is the hole that out-scopes all other formulas, and `LFs-[]` ensures that all labeled-formulas are 'used' for building the fully specified formula, and moreover, prevents us from

getting entangled in cyclic structures. If this goal succeeds, `Top` unifies with the resolved formula.

The constraints are checked each time after a hole is plugged. This is done with the help of `checkConstraints/3`. Its first argument is the label of the formula that is plugged, its second argument is the list of constraints, and its third argument the list of scoped formulas. In fact, it is just matter of working through the  $\leq$ -constraints and for each `leq(L,H)`, where the plugged label is identical with `L`, checking whether `H` is part of the scoped formulas.

```
checkConstraints(_, [], _).
checkConstraints(Label, [leq(L,H) | Constraints], Scoped) :-
    Label == L, !,
    member(Formula, Scoped), Formula == H,
    checkConstraints(Label, Constraints, Scoped).
checkConstraints(Label, [_ | Constraints], Scoped) :-
    checkConstraints(Label, Constraints, Scoped).
```

Note that we use the cut after identifying a relevant constraint. So if a constraint is violated, we force Prolog to backtrack and try a different plugging. And this is all there is to it.

Before putting the plugging algorithm into action, we will show how to build underspecified representations using our standard lexicon and grammar rules.

## Building Underspecified Representations

Building USRs is done with the tools we're already familiar way: using lambdas and  $\beta$ -conversion. For USRs, we are going to introduce lambdas for holes and labels as well. Further, we need a *merge*-operation for USRs, that combines two USRs to one big USR.

The way we construct USRs is basically an extension to our normal systematic way of constructing representations. To keep track of the holes and labels, we will decorate *each* USR-representation with two additional lambdas: the 'top hole', and the 'main label'. The top hole is the hole that closes the current scope domain. The main label is the label within the current scope domain that is out-scoped by all elements within its scope domain. Abstracting away from these two concepts, it is straightforward to combine USRs (incidentally, macro definitions might get complicated—drawing a picture often eases matters).

Let's introduce the semantic macro for a determiner:

```
detSem(uni, lambda(P, lambda(Q, lambda(H, lambda(L,
    merge(merge(usr([F, R, S],
```

```
[F:forall(X,R>S)],
[leq(F,H),leq(L,S)],P@X@H@R),Q@X@H@L))))).
```

The two additional lambdas for H and L close the scope domain of ‘every’. The quantifier itself gets label F with restriction **Restr** and nuclear scope **Scope**. Constraint `leq(F,H)` ensures that the quantifier is out-scoped by the top of the scope domain, and `leq(L,Scope)` says that its verbal argument is in its scope. The applications `P@X@H@R` and `Q@X@H@L` are crucial—these associate the restriction label of the quantifier with the label of the noun representation, and the top and hole label of the verb phrase argument.

Proper names or pronouns, on the other hand do not introduce holes, and therefore need not to bother about leq-constraints. A new top hole H and main label L are introduced and applied to its argument P.

```
pnSem(Sym,lambda(P,lambda(H,lambda(L,P@Sym@H@L))))).
```

Verbs introduce the ‘top’ hole and a leq-constraint between itself and the top. This is of importance for sentences where no quantifiers (or other scope-introducing elements) appear, as it establishes a clean link from the top element to the main label, that of the verb.

```
ivSem(Sym,lambda(X,lambda(H,lambda(L,usr([], [L:F], [leq(L,H)]))))) :-
  compose(F,Sym,[X]).
```

Underspecification allows us to be very flexible. We can use one and the same technique for both quantifiers and negation. Here is the semantic macro for verb negation:

```
modSem(neg,lambda(P,lambda(X,lambda(H,lambda(L,
  merge(usr([N,S], [N:(~S)], [leq(N,H),leq(L,S)]),P@X@H@L)))))).
```

There is one thing left we haven’t paid any attention to yet. It is combining smaller USRs to bigger ones, by carrying out the stipulated `merge/2` operations in the USR. Actually, this is not a big deal, and done as follows, using `append/3` from the library file.

```
mergeUSR(usr(D,L,C),usr(D,L,C)).

mergeUSR(merge(U1,U2),usr(D3,L3,C3)) :-
  mergeUSR(U1,usr(D1,L1,C1)),
  mergeUSR(U2,usr(D2,L2,C2)),
  append(D1,D2,D3),
  append(L1,L2,L3),
  append(C1,C2,C3).
```

As usual we implement a driver that grasps all the important predicates together. This one combines the plugging algorithm and the construction of USRs, displays the USR on the current output device as well as all the readings it has.

```

parse:-
  readLine(Sentence),
  d(Sem,Sentence,[]),
  betaConvert(merge(usr([Top,Main],[],[]),Sem@Top@Main),Reduced),
  mergeUSR(Reducd,usr(D,L,C)),
  printRepresentation(usr(D,L,C)),
  findall(Top,plugHole(Top,L-[],C,[]),Readings),
  printReadings(Readings).

```

Here is an example session:

```

?- parse.

> Every woman does not snort.

usr([A,B,C,D,E,F,G],
    [C:forall(H,D>E),D:woman(H),F:(~G),B:snort(H)],
    [leq(C,A),leq(B,E),leq(F,A),leq(B,G),leq(B,A)])

Readings:
1 forall(A,woman(A)> ~snort(A))
2 ~forall(A,woman(A)>snort(A))

```

## Evaluating Underspecification

So far we have formalized semantic underspecified representations and are able to deal with (quantifier) scope ambiguities. But how does this proposal relate to earlier accounts of scope ambiguities? Are there any benefits in using the new streamlined underspecified representation rather than stick to the old fashioned storage methods? The basic answer is that underspecification languages are more powerful: they exhibit far more descriptive potential than storage methods. To make this statement more clear, let's consider a concrete example sentence including three quantifiers:

(25) One criminal knows every owner of a hash bar.

With the tools developed in this chapter it is perfectly possible to represent the relative scopes of the three quantifiers fully underspecified. Moreover, it is possible to partially

specify relative scopes. For some (linguistic) reason, one might wish to express that ‘one criminal’ out-scopes ‘every owner’ and ‘a hash bar’, but that the relative scopes of the latter two quantifying constructs does not matter. We need not add new machinery to our formalism: we can use the  $\leq$ -constraint to state such requirements.

How do other approaches to quantifier scope fare with such requirements? Storage techniques (Cooper 1983; Keller 1988), to begin with, are not able to express such constraints. A store is a sequence of the core semantic representation and a list of the binding operators (the quantifiers) which scope is not fixed yet. In the process of constructing a store, quantified noun phrases can either enter the store or combine with the core semantic representation (and form a new core semantic representation, by means of in-situ quantification). At the end of the parse, the different ways in which the quantifiers are retrieved from the store and combined with the core semantic representation result in different readings (the last quantifier which is pulled off the store gets widest scope). Hence, to give a quantifier obligatory wide scope, the only way to pursue is to put it on the store, while performing in-situ application for the remaining quantifiers. But this presumes that the scope order of the remaining quantifiers is fixed!

### Software Summary of Chapter 3

`mainMontague.pl` A simple implementation of Montague’s approach to quantification. (page 223)

`englishGrammarMontague.pl` The revised grammar rules for Montague’s quantifier raising. (page 224)

`mainCooperStorage.pl` Implementation of Cooper Storage. Defines storage of noun phrases and retrieval of the store. (page 226)

`mainKellerStorage.pl` Implementation of Nested Storage (Keller). Defines storage of noun phrases and retrieval of the store. (page 228)

`semMacrosStorage.pl` Contains the semantic macros for Cooper and Keller storage. (page 230)

`pluggingAlgorithm.pl` The plugging algorithm for hole semantics. (page 231)

`mainPLU.pl` Implementation of predicate logic unplugged. (page 233)

`semMacrosPLU.pl` Contains the semantic macros for predicate logic unplugged. (page 234)

`mergeUSR.pl` Merging underspecified semantic representations. (page 236)

## Notes

More about quantifier scoping in general, and Montague's approach to quantification in particular, can be found in Dowty, Wall, and Peters 1981 or volume 2 of Gamut 1991b. Cooper storage was first used in Cooper 1975; a more refined version is presented in Cooper 1983. Nested Cooper storage is due to Keller (1988). This very readable paper introduces Cooper storage, explains where the problems lie, gives an example (involving an interaction between scope and anaphoric pronouns) which suggests that a simple check for free variables during retrieval isn't an adequate solution, and then introduces nested Cooper storage.

There are other approaches to quantifier scope ambiguity the reader should be aware of. Hobbs and Shieber 1987 provide an alternative to Cooper storage that overcomes some of the problems mentioned in this chapter. An improved version of their algorithm has been developed by Lewin (1990).

As we mentioned in the text, stores (and nested stores) are essentially a more abstract form of semantic representation—representations which encode multiple possibilities, without committing us to any particular choice. Viewed in this light, stores are ancestors of the current crop of *underspecification formalisms*, representation languages specifically designed to cope with ambiguity by avoiding overcommitment.

One of the first underspecified semantic representations were underspecified discourse representation structures (UDRSs) proposed by Reyle (1993). In fact, hole semantics can be seen as a generalization of this idea, not stuck to DRSs but compatible to all kinds of logical structures. Hole semantics is also applied in the machine translation system Verbmobil (Bos et al. 1996; Bos et al. 1998).

Probably the best way for the reader to find out more about the area of underspecification is to consult the recent collection edited by Van Deemter and Peters (Van Deemter and Peters 1996).

# Chapter 4

## Propositional Inference

In this chapter we turn to the second major theme of the book, namely:

*How can we use the logical representations of natural language expressions to automate the process of drawing inferences?*

Recall from Chapter 1 that a valid formula is a formula that cannot be falsified in any model, and that a valid argument (or valid inference) is an argument such that whenever all the premisses are true in some model, the conclusion is true in that model also. These concepts are the fundamental ones underlying the idea of logical inference, and so we need a way of getting to grips with them computationally. But there is a problem. Both concepts are semantic: that is, they are defined in terms of models. Moreover, they use models in a very strong way: their definitions refer to the class of *all* models. Now, the class of all models is a very large and abstract entity. Certainly we cannot put all models in the computer (there are infinitely many of them, most of which are infinite) and check whether an argument is valid by checking its premisses and conclusions in them all. So, if we want programs that perform logical inference, we will have to look for another approach.

Fortunately, alternatives are available. The branch of logic called *proof theory* studies *syntactically* defined inference methods. That is, proof theorists are interested in inference methods which only make use of the syntactic structure of sentences; models play no role. Of course, proof theoretic methods must always be *justifiable* in semantic terms. That is, if someone asks why some proposed syntactic proof method really is a way of performing genuine logical inference—not just some bizarre way of manipulating logical symbols—it must be possible to show that the method is faithful to the fundamental semantic concepts of validity. Nonetheless, *using* proof-theoretic methods requires no appeal to semantic concepts; only syntactic manipulation of formulas is required. Since we are interested in automating inference, it is clearly sensible to try and make use of such techniques, for syntax is pleasantly concrete—it’s something that a computer can easily get to grips with.

Proof theorists have studied many different proof methods. Among the better known ones are axiomatic systems, natural deduction systems, resolution-based systems, sequent calculi, and the method we shall discuss here: *tableaux systems*. The various proof methods were developed for different purposes, and have different strengths and weaknesses. For example, axiomatic systems are excellent if one wants to study provability at an abstract level, but awful to actually use. Natural deduction systems, on the other hand, are nice and easy for people to use (as their name suggests, they try to capture something of what is involved when a human being goes about proving something), but, precisely because they demand human insight, are not the best choice for automated theorem proving. Resolution, on the other hand, has proved to be the key method for automated theorem proving (Prolog is based on it), but it is a ‘machine oriented’ rather than a ‘human oriented’ approach. We have chosen to work with tableaux systems because they offer the following blend of advantages:

1. Tableaux are a very intuitive proof method. The tableaux method is certainly syntactic, nonetheless it is based on utterly transparent semantic intuitions—indeed, tableaux are often called *semantic tableaux*. They are certainly a ‘human oriented’ approach to inference.
2. Although intuitively natural, the process of finding a tableaux proof does not *depend* on human insight. Certainly human insight can streamline the process of performing tableaux inferences; nonetheless, the basic mechanism is suitable for machine implementation. Indeed, tableaux proof systems are relatively simple to implement, and, resolution aside, are one of the more popular automated theorem proving methods.
3. The tableaux method can be adapted to many different logics, such as higher-order and non-classical logics. The basic ideas are relatively robust, and the reader who masters them in the case of first-order logic has actually mastered ideas of far wider applicability.
4. Tableaux systems are more than just theorem provers: they can also be regarded as *model building tools*. (This is another reason why they are sometimes called semantic tableaux.) For some applications this additional ability is useful.

In this chapter we are going to develop the tableaux method for propositional languages. Recall from Chapter 1 that propositional languages are essentially a user-friendly notation for the quantifier-free fragment of first order languages. It will turn out that this is a very important fragment to examine, for in the next chapter we shall see how to efficiently reduce the tableaux method for a full first-order language to the tableaux method for its propositional fragment.

## 4.1 Propositional Tableaux

The key intuition underlying the tableaux proof technique revolves around the following *semantic* question:

*Suppose we are given a formula, and one of the truth values TRUE or FALSE. Is it possible to find a model in which the given formula has the given truth value?*

The tableaux method is essentially a *syntactic* way of answering this question. More precisely, a tableaux proof is a *systematic* check, making use of only syntactic concepts, which lets us know whether or not it is possible to build a model in which some given formula is true or false.

Suppose that we had such a systematic check at our disposal. (We soon will have.) Why would it be useful? First, note that it would give us a way to test formulas for validity: ‘valid’ means ‘true in all models’, so a formula is valid if and only if it is not possible to falsify it in any model. Hence, a formula  $\phi$  would be valid iff the systematic method told us that there was no way to build a model that falsified  $\phi$ .

Second, note that such a method would also give us a way of performing logical inference. For suppose we are given  $\phi_1, \dots, \phi_n$  are premisses, and we wish to judge whether the argument to the conclusion  $\psi$  is valid or not. That is, we wish to know whether or not

$$\phi_1, \dots, \phi_n \models \psi.$$

Now, by the Deduction Theorem (discussed in Chapter 1), this argument is valid precisely when

$$\models \phi_1 \wedge \dots \wedge \phi_n \rightarrow \psi,$$

that is, when  $\phi_1 \wedge \dots \wedge \phi_n \rightarrow \psi$  is a valid formula. In short, the problem of deciding whether arguments are valid is reducible to the problem of deciding whether formulas are valid. So, given a method of determining whether a formula is valid, we can use it for judging the validity of arguments as well.

Thus such a systematic check for the existence of satisfying or falsifying models would certainly be worth having, and this is exactly what tableaux systems give us. But what is a tableaux system, and how do they systematically check for the existence of suitable models? In the remainder of this section we informally introduce the key ideas involved. We do this by presenting three examples of tableaux proofs, taking care to point out the underlying semantic intuitions. In the following section we will make our discussion more precise.

Consider the formula  $p \vee \neg p$ . This is a validity—we certainly can’t falsify it—but what would a systematic search for a falsification look like? Now, we’ve already seen one answer

to this question—simply fill out its truth table! But this answer isn't very appealing. For a start, it's not an answer we can generalise to first-order languages. Moreover, while a truth table is easy to fill out for  $p \vee \neg p$ , the truth table for a formula containing 8 different propositional variables contains 256 lines, while the table for a formula containing 20 variables contains  $2^{20}$  lines, which is too large for comfort. So we won't bother with truth tables—instead, we'll develop a number of *tableaux expansion rules*. These rules tell us how to make complex formulas true (or false) by breaking them down into their component formulas and giving the components the appropriate truth value. Let's see what sort of rules are needed, and how to use them, by constructing a tableaux proof of  $p \vee \neg p$ .

We want to try and falsify  $p \vee \neg p$ , so let's introduce a piece of notation to express this goal. Writing  $F\phi$ , where  $\phi$  is any formula, will mean that we want to make  $\phi$  false. Similarly, writing  $T\phi$  will mean that we want to make  $\phi$  true. ( $T$  and  $F$  are called *signs*, and a formula preceded by a sign is called a *signed formula*.) Thus, as we are going to try to falsify  $p \vee \neg p$ , our initial goal is:

$$F(p \vee \neg p).$$

This rather trivial looking object is our first example of a tableau. Actually, when writing out tableaux by hand, it is handy to include a little extra book-keeping information, such as line numbers. So, in practice we'd tend to write the above tableau as:

$$1 \quad F(p \vee \neg p)$$

How do we proceed? Essentially we use the tableaux expansion rules to smash the signed formula into smaller and smaller pieces until we reach the atomic level. So, what expansion rule should we apply here? Obviously we need a rule that tells us how to *falsify a disjunction*. The required rule is clear: to make a disjunction false, falsify both disjuncts. So, applying this rule—let's call it  $F_\vee$ —we expand our one line tableau to a three line tableau as follows:

$$\begin{array}{lll} 1 & F(p \vee \neg p) & \checkmark \\ 2 & Fp & 1, F_\vee \\ 3 & F\neg p & 1, F_\vee \end{array}$$

Here, lines 2 and 3 are the extra information we have deduced by applying the  $F_\vee$  rule. The third column contains more book-keeping information: the  $\checkmark$  symbol in line 1 records the fact that we've applied the appropriate rule to line 1, while the annotations '1,  $F_\vee$ ' in lines 2 and 3 record the fact that these lines were obtained from line 1 using rule  $F_\vee$ .

What next? In fact, there's only one more thing we can do. We've already applied a rule to line 1, so we've finished with that. Furthermore, line 2 tells us something about *atomic* information (namely that we need to make  $p$  false). This is simply a blunt fact, not something that can be further analysed. Thus only line 3 offers us the possibility of further

progress; it tells us that we need to falsify the negation of  $p$ . So, we need an expansion rule that tells us how to do this. Again, the required rule is clear: to make the negation of a formula false, make the formula itself true. So, applying this rule—call it  $F_{\neg}$ —we can expand our three line tableau to a four line tableau as follows:

1	$F(p \vee \neg p)$	$\checkmark$
2	$Fp$	$1, F_{\vee}$
3	$F\neg p$	$1, F_{\vee}, \checkmark$
4	$Tp$	$3, F_{\neg}$

Note that we have marked line 3 with a  $\checkmark$  (thus recording that the applicable rule has been applied) and have indicated that line 4 was obtained from line 3 using  $F_{\neg}$ .

There are two important observations that must be made about this tableau. First, it is *rule saturated*. That is, we cannot expand it any more. Either we've already applied the applicable rule (lines 1 and 3), or the line contains instructions about what to do with atomic information (lines 2 and 4). Second, the tableau is *closed*. That is, it contains contradictory instructions. The tableau tells us that if we want to falsify  $p \vee \neg p$ , we have to make  $p$  false (line 2) and  $p$  true (line 4). As this is impossible, and as it should be pretty clear that the above tableau really does indicate all possible ways falsifying  $p \vee \neg p$ , we conclude that this formula is valid. This closed tableau is called a *tableaux proof* of  $p \vee \neg p$ .

The previous example is a perfectly good tableaux proof, but it's also just about the simplest one the reader is ever likely to see. So let's consider a slightly more demanding task: testing  $\neg(q \wedge r) \rightarrow (\neg q \vee \neg r)$  for validity.

Just as in the previous example, our initial goal is to try and falsify the given formula. Thus our initial tableau is:

$$1 \quad F\neg(q \wedge r) \rightarrow (\neg q \vee \neg r)$$

We need to falsify an implication, so we need an expansion rule that tells us how to do this. Again, the required rule is clear: to falsify an implication, make the antecedent true and the consequent false. Applying this rule—let's call it  $F_{\rightarrow}$ —yields the following tableau:

1	$F\neg(q \wedge r) \rightarrow (\neg q \vee \neg r)$	$\checkmark$
2	$T\neg(q \wedge r)$	$1, F_{\rightarrow}$
3	$F(\neg q \vee \neg r)$	$1, F_{\rightarrow}$

Now, line 3 demands that we falsify a disjunction. We've already met the required expansion rule, namely  $F_{\vee}$ . Applying it to line 3 yields:

1	$F\neg(q \wedge r) \rightarrow (\neg q \vee \neg r)$	$\checkmark$
2	$T\neg(q \wedge r)$	$1, F_{\rightarrow}$
3	$F(\neg q \vee \neg r)$	$1, F_{\rightarrow}, \checkmark$
4	$F\neg q$	$3, F_{\vee}$
5	$F\neg r$	$3, F_{\vee}$

Now at this point the alert reader should be saying “Hold on a minute! Why are we free to apply this rule to line 3? Sure, the rule fits—but look at line 2. There’s a formula there that we need to make true. Don’t we need to take care of that first?”

A sensible question, but the answer is: *no, we don’t*. One of the pleasant things about tableaux is that we are free to apply applicable rules in any order we like. Yes, we could have applied the relevant rule to line 2 at this point, had we wanted to—but we’re equally free to apply a rule to line 3, just as we did above. Tableaux rules just tell us what we’re *permitted* to do to expand a tableau; we’re not forced to apply expansion rules in any particular order.

So let’s move on. Note that both lines 4 and 5 ask us to falsify a negated formula. Again, we have already met the relevant rule, namely  $F_{\neg}$ . Applying it first to line 4, and then to line 5 (a completely arbitrary ordering choice) yields:

1	$F\neg(q \wedge r) \rightarrow (\neg q \vee \neg r)$	$\checkmark$
2	$T\neg(q \wedge r)$	$1, F_{\rightarrow}$
3	$F(\neg q \vee \neg r)$	$1, F_{\rightarrow}, \checkmark$
4	$F\neg q$	$3, F_{\vee}, \checkmark$
5	$F\neg r$	$3, F_{\vee}, \checkmark$
6	$Tq$	$4, F_{\neg}$
7	$Tr$	$5, F_{\neg}$

Let’s now deal with line 2. (In fact, there is nothing else we can do.) We need to make a negation true. The required rule is clear: to make the negation of a formula true, make the formula itself false. So, applying this rule—call it  $T_{\neg}$ —we can expand our tableau to obtain:

1	$F\neg(q \wedge r) \rightarrow (\neg q \vee \neg r)$	$\checkmark$
2	$T\neg(q \wedge r)$	$1, F_{\rightarrow}, \checkmark$
3	$F(\neg q \vee \neg r)$	$1, F_{\rightarrow}, \checkmark$
4	$F\neg q$	$3, F_{\vee}, \checkmark$
5	$F\neg r$	$3, F_{\vee}, \checkmark$
6	$Tq$	$4, F_{\neg}$
7	$Tr$	$5, F_{\neg}$
8	$F(q \wedge r)$	$2, T_{\neg}$

Now we have to deal with line 8, which asks us to falsify a conjunction. Doing so leads us to the first real complication in the story we have been telling. The point is this: there's not just one way of making a conjunction false, there's two. Making either conjunct false will falsify the whole formula. As tableaux are meant to be *systematic* searches for falsifications, we're going to have to examine both possibilities. Thus the relevant expansion rule—call it  $F_{\wedge}$ —is going to yield two alternative ways of expanding the tableau, and we're going to have to keep track of both.

$F_{\wedge}$  is our first example of a *disjunctive* (or *branching*) expansion rule; we'll encounter more such rules in the following section. Because of such rules, tableaux *won't* generally consist of a single straight line down the page (that is, they're no longer going to consist of a single *branch*, to use the official terminology). Rather, they will be tree-like structures, possibly containing many branches. In the present case, what we get after applying  $F_{\wedge}$  is:

1	$F\neg(q \wedge r) \rightarrow (\neg q \wedge \neg r)$	$\checkmark$
2	$T\neg(q \wedge r)$	$1, F_{\rightarrow}, \checkmark$
3	$F(\neg q \wedge \neg r)$	$1, F_{\rightarrow}, \checkmark$
4	$F\neg q$	$3, F_{\vee}, \checkmark$
5	$F\neg r$	$3, F_{\vee}, \checkmark$
6	$Tq$	$4, F_{\neg}$
7	$Tr$	$5, F_{\neg}$
8	$F(q \wedge r)$	$2, T_{\neg}, \checkmark$
<hr/>		
9	$Fq$	$8, F_{\wedge}$
10	$Fr$	$8, F_{\wedge}$

That is, we have recorded two distinct possibilities: we must either falsify  $q$ , or falsify  $r$ .

But let's return to our tableaux proof. What do we do next? Actually, we've finished: our two-branch tableau is rule-saturated, as the reader can easily check. So, after all that, is  $\neg(q \wedge r) \rightarrow (\neg q \wedge \neg r)$  a validity or not? Yes, it is. This is because the rule-saturated tableau we produced is *closed*, which means that *all the branches it contains are closed*. To see this, note that the left-hand branch is closed because it contains the contradictory instructions  $Fq$  (at line 9) and  $Tq$  (at line 6); whereas the right-hand branch is closed because it contains  $Fr$  (at line 9) and  $Tr$  (at line 7). This closed tableau is a tableaux proof of  $\neg(q \wedge r) \rightarrow (\neg q \wedge \neg r)$ .

Let's consider a final example to illustrate what happens if the formula we are working with is *not* a validity. Now, the formula  $(p \wedge q) \rightarrow (r \vee s)$  is certainly not valid; what happens when we try and falsify it using the tableaux method?

As usual, the first step simply states our goal, namely :

$$1 \quad F(p \wedge q) \rightarrow (r \vee s)$$

As we need to falsify an implication, the relevant expansion rule is  $F_{\rightarrow}$ :

1	$F(p \wedge q) \rightarrow (r \vee s)$	$\checkmark$
2	$T(p \wedge q)$	$1, F_{\rightarrow}$
3	$F(r \vee q)$	$1, F_{\rightarrow}$

Now line 2 requires us to make a conjunction true. The expansion rule  $T_{\wedge}$  required is clear: we must make both conjuncts true. Applying  $T_{\wedge}$  yields:

1	$F(p \wedge q) \rightarrow (r \vee s)$	$\checkmark$
2	$T(p \wedge q)$	$1, F_{\rightarrow}, \checkmark$
3	$F(r \vee q)$	$1, F_{\rightarrow}$
4	$Tp$	$2, T_{\wedge}$
5	$Tq$	$2, T_{\wedge}$

Now let's deal with line 3. The relevant rule is  $F_{\vee}$ . Applying it yields:

1	$F(p \wedge q) \rightarrow (r \vee s)$	$\checkmark$
2	$T(p \wedge q)$	$1, F_{\rightarrow}, \checkmark$
3	$F(r \vee q)$	$1, F_{\rightarrow}, \checkmark$
4	$Tp$	$2, T_{\wedge}$
5	$Tq$	$2, T_{\wedge}$
6	$Fr$	$3, F_{\vee}$
7	$Fs$	$3, F_{\vee}$

But now the expansion process halts. This tableau is rule-saturated: we've applied the relevant rules to line 1–3, while lines 4–7 simply stipulate what has to be done with atomic information. But note that there is crucial difference between this tableau and the previous rule-saturated tableaux we have seen: the single branch in this tableau is not closed, it's *open*. That is, it does *not* contain contradictory instructions. In fact, it gives us very sensible instructions indeed: lines 4–7 tell us to make  $p$  true,  $q$  true,  $r$  false, and  $s$  false. As the reader can easily check, doing this falsifies  $(p \wedge q) \rightarrow (r \vee s)$ , thus this formula is *not* a validity.

More generally, a rule-saturated tableau is called *open* iff it contains at least one open branch. If we obtain an open tableau when we try to falsify some formula, this means that the formula is *not* a validity. Moreover, just as in the previous example, every open branch on the open tableau actually contains an explicit 'falsification recipe' for the formula: we falsify it by assigning truth values to the atomic symbols in the the way the open branch stipulates. To put it another way, open branches of rule-saturated tableaux tell us to build a model that falsifies the formula we started with.

The reader should now have a fairly clear grasp of the main ideas and intuitions underlying tableaux proofs, so let's now discuss the method more systematically. We begin by listing

the 8 main expansion rules, and classifying them into three types: *unary rules*, *conjunctive rules*, and *disjunctive rules*. This classification isn't vital, but it will help us keep the implementation neat.

For each Boolean connective  $B$ , we have two tableaux rules,  $T_B$  and  $F_B$ .  $T_B$  tells us how to make a formula with  $B$  as its main connective true, while  $F_B$  tells us how to make it false. The rules for negation,  $T_{\neg}$  and  $F_{\neg}$ , are the simplest:

$$\frac{T\neg\phi}{F\phi} \qquad \frac{F\neg\phi}{T\phi}$$

These rules should be read from top to bottom. Given the examples discussed in the previous section, their meaning should be reasonably clear. In each rule, the signed formula above the horizontal line is the *input* to the rule, and the signed formula below it is the *output*. For example,  $T_{\neg}$  takes as input signed formulas of the form  $T\neg\phi$ , and returns as output signed formulas of the form  $F\phi$ . Similarly,  $F_{\neg}$  takes as input signed formulas of the form  $F\neg\phi$  and returns as output signed formulas of the form  $T\phi$ . In what follows, we shall call these two rules our *unary rules*. This is simply shorthand for the fact that both rules return a single formula as output.

The rules for the binary connectives  $\wedge$ ,  $\vee$  and  $\rightarrow$  are rather more interesting. Here are  $T_{\wedge}$  and  $F_{\wedge}$ ,  $F_{\vee}$  and  $T_{\vee}$ , and  $F_{\rightarrow}$  and  $T_{\rightarrow}$ , respectively:

$$\begin{array}{cc} \frac{T(\phi \wedge \psi)}{T\phi} & \frac{F(\phi \wedge \psi)}{F\phi \mid F\psi} \\ T\psi & \\ \\ \frac{F(\phi \vee \psi)}{F\phi} & \frac{T(\phi \vee \psi)}{T\phi \mid T\psi} \\ F\psi & \\ \\ \frac{F(\phi \rightarrow \psi)}{T\phi} & \frac{T(\phi \rightarrow \psi)}{F\phi \mid T\psi} \\ F\psi & \end{array}$$

Again, all six rule should be read from top to bottom, the top being the input to the rule, the bottom the output. We shall call the three rules in the left-hand column (that is,  $T_{\wedge}$ ,  $F_{\vee}$ , and  $F_{\rightarrow}$ ) *conjunctive rules*. The three rules on the right-hand side (that is,  $F_{\wedge}$ ,  $T_{\vee}$ , and  $T_{\rightarrow}$ ) are called *disjunctive rules*. Note that each of  $\wedge$ ,  $\vee$  and  $\rightarrow$  gives rise to a pair of rules, one of which is conjunctive, the other disjunctive. Both conjunctive and disjunctive rules return two formulas as output—however, as we have already seen, they differ in the effect they have on tableaux. In particular, use of a disjunctive rule splits the branches of the tableaux containing the input formula into distinct branches, each of which records one of the two alternative output formula.

In the discussion that follows, we'll assume that we only have these 8 rules at our disposal. However, the reader should be aware that it is very straightforward to give expansion rules for other connectives, though such rules won't always fit into our three way classification. For example, it can be useful to have the expansion rules for  $\leftrightarrow$  at our disposal. Here are the required rules:

$$\frac{T(\phi \leftrightarrow \psi)}{T\phi \mid F\phi \quad T\psi \mid F\psi} \qquad \frac{F(\phi \leftrightarrow \psi)}{T\phi \mid F\phi \quad F\psi \mid T\psi}$$

Note that for this connective we *don't* obtain a neat pair of rules, one of which is conjunctive, the other disjunctive, as we did for  $\wedge$ ,  $\vee$  and  $\rightarrow$ . Moreover, though both rules are 'disjunctive' in the sense that both force us to split tableau branches, these rules yield 4 output formulas, 2 for each possible branch. The exercises below ask the reader to develop expansion rules for some other connectives.

Now that we know what our expansion rules are, let's make our previous discussion of tableaux and tableaux proofs a little more rigorous.

A (propositional) *tableau* is simply a tree, each of whose nodes is a signed (propositional) formula. A *branch* of a tableau is simply a branch of such a tree—that is, a collection of nodes (that is, signed formula) that contains exactly one leaf node together with all the nodes which dominate it.

An *initial tableau*—that is, the kind of tableau with which we start the tableaux expansion process—is a tableau that has only a single branch. The reader may be slightly surprised by this definition. Isn't it too general? Why don't we simply define an initial tableau to be a tableau consisting of a single signed formula of the form  $F\phi$ ? Actually we *could* use this more specific definition—but, as we shall later see, the slightly more general definition given is rather useful.

We carry out the tableau expansion process as follows. Given a tableau, try to find a node in it that (a) isn't a signed atomic formula, and (b) to which we haven't already applied an expansion rule. Let's call such nodes *unexpanded nodes*. If there are no unexpanded nodes, we can't do anything: we have a *rule-saturated* tableau and are finished. So suppose there is at least one unexpanded node. This node has the form  $S\phi$ , where  $S$  is either  $T$  or  $F$ , and  $\phi$  is a propositional formula. Moreover, as  $\phi$  is not atomic, it has a main connective  $B$ , where  $B$  is one of the connectives  $\neg$ ,  $\wedge$ ,  $\vee$ , or  $\rightarrow$ . We can then 'read off' the required rule: we have to apply rule  $S_B$ .

What happens when we apply a rule to a node? That depends on whether the rule is unary, disjunctive, or conjunctive. If the rule is unary, we extend every branch containing the input node by adding on the output formula of the rule as the new leaf node. If the rule is conjunctive, we extend every branch containing the input node by adding on, again at the leaf node, both output formula of the rule. Finally, if the rule is disjunctive, we extend every branch containing the input node to two distinct branches, one containing

each of two choices of output formulas. Again, both the required additions are carried out at the leaf node of the original branches.

The basic idea of tableau expansion should be clear from the examples we discussed earlier, but there is one point worth emphasizing. A signed formula may belong to several branches. (For example, the root node belongs to every branch of a tableau.) When we perform an expansion, we have to extend *every* branch on which the input formula lies in the appropriate way. For example, consider the following tree:

If we expand the indicated node  $T(\phi \vee \psi)$ , we obtain:

The tableau expansion process starts when we are given an initial tableau. We apply rules to the initial tableau, and then to the tableaux obtained by earlier rule applications, and so on, until it is not possible to apply any more rules. As we discussed earlier, we can apply the rules in any order we like. The tableau expansion process stops when it is not possible to apply any more rules, that is, when we obtain a rule-saturated tableau. Here an important question looms: is the expansion process always guaranteed to stop? Yes, it is. We will point out why later in the chapter—but it would be a good idea for the reader to try figuring this out now unaided.

We are now almost ready to say what a *tableau proof* is. First, a branch of a tableau is *closed* if it contains both  $T\phi$  and  $F\phi$ , where  $\phi$  is some formula. A branch that is not closed is called *open*. A tableau is closed if *every* branch it contains is closed, and open if it contains *at least one* open branch. Now for the key definition:

*A formula  $\phi$  is tableaux-provable (or, more simply: provable) if and only if it is possible to expand the initial tableau consisting of a single node  $F\phi$  to a closed tableau. We use the notation  $\vdash \phi$  to indicate that  $\phi$  is provable.*

And that's the (propositional) tableaux method. To conclude our discussion, two remarks.

First, note that the tableaux method really is a purely *syntactic* method. This should be clear. If we want to test whether  $\phi$  is provable we have to start with the initial tableau  $F\phi$ , and then try and expand it to a closed tableau. The entire expansion process is governed by syntactic ideas. For example, when we expand a node, by simply looking at its sign and main connective we know which rule to apply. Moreover, closure is a purely syntactic concept: it simply amounts to looking for items of the form  $T\phi$  and  $F\phi$  on some branch. Of course, as our presentation has tried to emphasize, the tableaux method is driven by clear *semantic* ideas. Nonetheless, *using* the method doesn't require any semantic insight at all. Even if we didn't know what the signs  $T$  and  $F$  were meant to stand for—or indeed, what  $\neg$ ,  $\wedge$ ,  $\vee$ , and  $\rightarrow$  were meant to represent—we would still have a well defined way of manipulating logical formulas. It would probably be an exaggeration to claim that we could train a monkey to carry out tableaux proofs, but as we shall see below, we can certainly implement them in Prolog rather easily.

The second point concerns our definition of initial tableaux. Why did we opt for the general definition, rather simply stating that initial tableau always have the form  $F\phi$ ? Simply because, as we shall now see, by using different initial tableau we can use tableaux for different purposes.

First, we can use tableaux to *directly* test whether arguments are valid. For example, suppose we wanted to test

$$\phi_1, \dots, \phi_n \models \psi,$$

for validity. Now, as we pointed out earlier, by the Deduction Theorem this is equivalent to testing whether  $\phi_1 \wedge \dots \wedge \phi_n \rightarrow \psi$  is a valid formula, thus we could simply try using the tableaux method to falsify this formula. But there is a more direct way. An argument is valid if and only if whenever all the premisses are true, the conclusion is true also. Hence, to test whether the above argument is valid, we could form the initial tableau:

$$\begin{array}{c} T\phi_1 \\ \cdot \\ \cdot \\ \cdot \\ T\phi_n \\ F\psi \end{array}$$

That is, we simply use the tableau method to see whether it is possible to make all the premisses true and the conclusion false. If we *can't* do this—that is, if we obtain a closed tableau—the argument is valid.

But we can do more with tableaux than simply testing whether formulas and arguments are valid: we can use them as a tool for telling us how to build models. To give a very trivial example, suppose we wanted to know exactly how to make the formula  $\neg p \wedge (r \vee q)$

true. The tableau method will tell us how to do this. As our initial tableau we take:

$$T\neg p \wedge (r \vee q).$$

That is, we are simply asking: “How do we make this formula true?” To get an answer, all we have to do is carry out the expansion process in the usual way:

1	$T\neg p \wedge (r \vee q)$	$\checkmark$
2	$T\neg p$	$1, T_{\wedge}, \checkmark$
3	$T(r \vee q)$	$1, T_{\wedge}, \checkmark$
4	$Fp$	$2, T_{\neg}, \checkmark$
<hr/>		
5	$Tr \quad 3, T_{\vee}$	
6	$Tq \quad 3, T_{\vee}$	

This tableaux is rule-saturated and contains two open branches. The left hand branch tells us that one way to make the input formula true is to make  $p$  false and  $r$  true, while the right hand branch tells us that there is also another way to achieve this, namely by making  $p$  false and  $q$  true.

**Exercise 4.1.1** Show that the following formula's are all provable:

1.  $\neg\neg p \rightarrow p$
2.  $((p \rightarrow q) \rightarrow p) \rightarrow p$
3.  $(\neg p \rightarrow \neg q) \rightarrow (q \rightarrow p)$
4.  $p \leftrightarrow (p \wedge (q \vee p))$
5.  $(p \vee (q \wedge r)) \leftrightarrow ((p \vee q) \wedge (p \vee r))$

**Exercise 4.1.2** The connectives *nand* and *nor* are defined by the following truth tables:

$p$	$q$	$p \text{ nand } q$	$p \text{ nor } q$
TRUE	TRUE	FALSE	FALSE
TRUE	FALSE	TRUE	FALSE
FALSE	TRUE	TRUE	FALSE
FALSE	FALSE	TRUE	TRUE

Give the tableaux expansion rules for both connectives.

**Exercise 4.1.3** There are two ways of using tableaux to show that an argument is valid: the indirect method that appeals to the Deduction Theorem, and the direct method just discussed. Explain why both methods give rise to the same result.

## 4.2 Implementing Propositional Tableaux

We shall represent tableaux in Prolog as lists containing lists of signed formulas. Signed formulas are represented as normal Prolog terms with functors  $\mathbf{f}$  and  $\mathbf{t}$  of arity 1. For example, the following is the Prolog representation of a tableau:

$$[[\mathbf{f}(p \rightarrow q)]].$$

This represents the tableau with just one branch, namely a branch containing the single signed formula  $F(p \rightarrow q)$ .

Here's a second example:

$$[[\mathbf{t}(p \ \& \ q), \ \mathbf{f}(p \ \& \ r)]].$$

Again, this represents a tableau with just one branch. This time, however, the branch contains *two* signed formulas, namely  $T(p \wedge q)$  and  $F(p \wedge q)$ .

The Prolog implementation of propositional tableaux consists of a small collection of predicates which manipulate such lists in accordance with the tableaux expansion rules. For example, the list just given contains  $\mathbf{t}(p \ \& \ q)$ . Now, to make a conjunction true, we use expansion rule  $T_{\wedge}$ , which in this case tells us to add  $Tp$  and  $Tq$  to the given branch. It is easy to mimic the required expansion in Prolog: all we have to do is define a predicate which when given the previous list as input, returns the following one as output:

$$[[\mathbf{t}(p), \ \mathbf{t}(q), \ \mathbf{f}(p \ \& \ r)]].$$

Note two things. First, as expected, the output list contains  $\mathbf{t}(p)$  and  $\mathbf{t}(q)$ . Second, it does *not* contain  $\mathbf{t}(p \ \& \ q)$ . Why is this? Because once the relevant expansion rule has been applied to some formula, that formula is no longer relevant and can be removed. That is, removal of signed formulas from lists is the Prolog analog of the  $\surd$  marking we used in our handwritten proofs.

Note that our new list contains  $\mathbf{f}(p \ \& \ r)$ , thus we can process it even further. Now, the rule for falsifying a conjunction is  $F_{\wedge}$ , a *disjunctive* rule. How are disjunctive expansions to be handled in Prolog? Again, the basic idea is very simple. To handle  $F_{\wedge}$ , for example, we need simply define a predicate which when given the previous list as input, return the following one as output:

$$[[\mathbf{t}(p), \ \mathbf{t}(q), \ \mathbf{f}(p)], \ [\mathbf{t}(p), \ \mathbf{t}(q), \ \mathbf{f}(r)]]$$

Note that this list contains *two* lists. It is thus the Prolog representation of a tableau containing *two* branches, namely the tableau with the signed formulas  $Tp$ ,  $Tq$  and  $Fp$  on one (closed) branch, and the formulas  $Tp$ ,  $Tq$  and  $Fr$  on the other.

Note that this approach to disjunctive rules differs from our handwritten approach. Our Prolog code make two copies of the branch, one for each of the two disjunctive possibilities. This is somewhat heavy handed—but it makes the code easy to understand. On the other hand, when writing out proofs by hand we want to cut down the writing needed as much as possible—hence our use of tree-like structures in which the information common to two branches is shared. Of course, by taking trees as the fundamental data structure, it is possible to implement this kind of structure sharing in Prolog, and doing so is an extremely valuable exercise.

Summing up, our Prolog implementation is based round the representation of tableaux as lists containing lists of signed formulas. Each list of signed formula corresponds to a branch. We carry out expansions by manipulating these lists of signed formulas in the appropriate way. In particular, conjunctive (and unary) expansions will be carried out by taking the list representation of a branch, removing the relevant conjunctive (or unary) signed formula, and adding its component(s) to the list. Disjunctive expansions are carried out in much the same way, save that the process returns *two* lists, one containing each of the two possible components. Incidentally, the program given below does not handle the  $\leftrightarrow$  connective; a good way of testing your understanding of the code is modify it so that it does.

Let's go systematically through the program. The outermost predicate is called **saturate**. This takes a single argument, a tableau, which it recursively attempts to rule-saturate with the help of the **expand** predicate. Note that base clause of **saturate** calls the **closed** predicate, which tests whether the input tableau is closed. By making this test here, we ensure that once a closed tableau is found, no further attempt is made to apply expansion rules.

```
saturate(Tableau):-
    closed(Tableau).

saturate(OldTableau):-
    expand(OldTableau,NewTableau),
    saturate(NewTableau).
```

The **closed** predicate is recursively defined in the expected way. To ground the recursion, the empty list is defined to be closed. A tableau containing branches can then be tested for closure by recursively peeling off its branches and checking for occurrences of both **t(X)** and **f(X)** for some formula **X**.

```
closed([]).

closed([Branch|Rest]):-
    member(t(X),Branch),
```

```
member(f(X),Branch),
closed(Rest).
```

The `expand/2` predicate is a high level ‘organisational’ predicate: it simply works its way recursively through all the branches in the input tableau, looking for branches to which one of the predicates `unaryExpansion`, `conjunctiveExpansion`, or `disjunctiveExpansion` apply. The fourth, recursive clause of `expand/2` takes the next branch of the tableau if no more expansions can be carried out to the current branch.

```
expand([Branch|Tableau],[NewBranch|Tableau]):-
    unaryExpansion(Branch,NewBranch).

expand([Branch|Tableau],[NewBranch|Tableau]):-
    conjunctiveExpansion(Branch,NewBranch).

expand([Branch|Tableau],[NewBranch1,NewBranch2|Tableau]):-
    disjunctiveExpansion(Branch,NewBranch1,NewBranch2).

expand([Branch|Rest],[Branch|Newrest]):-
    expand(Rest,Newrest).
```

The expansion predicates do the real work. Both the predicates `unaryExpansion` and `conjunctiveExpansion` have two arguments, namely an ‘input branch’, and an ‘output branch’, while `disjunctiveExpansion` takes three arguments, an input branch and *two* output branches. All three predicates look for the occurrence of the appropriate type of signed formula (namely `unary`, `conjunctive`, and `disjunctive` respectively) as the first item in the input branch, use the library predicate `removeFirst/3` to remove that occurrence, and then build the required new branch (or branches, in the case of disjunctive formulas) out of the component (or components) of the signed formula.

```
unaryExpansion(Branch,[Component|Temp]):-
    unary(SignedFormula,Component),
    removeFirst(SignedFormula,Branch,Temp).

conjunctiveExpansion(Branch,[Comp1,Comp2|Temp]):-
    conjunctive(SignedFormula,Comp1,Comp2),
    removeFirst(SignedFormula,Branch,Temp).

disjunctiveExpansion(Branch,[Comp1|Temp],[Comp2|Temp]):-
    disjunctive(SignedFormula,Comp1,Comp2),
    removeFirst(SignedFormula,Branch,Temp).
```

Thus, it only remains to define what **conjunctive**, **disjunctive**, and **unary** signed formula are:

```

conjunctive(t(X & Y),t(X),t(Y)).
conjunctive(f(X v Y),f(X),f(Y)).
conjunctive(f(X > Y),t(X),f(Y)).

disjunctive(f(X & Y),f(X),f(Y)).
disjunctive(t(X v Y),t(X),t(Y)).
disjunctive(t(X > Y),f(X),t(Y)).

unary(t(~X),f(X)).
unary(f(~X),t(X)).

```

And that's that. Of course, using **saturate** directly is a little clumsy, and it is preferable to call it in a slightly more user-friendly way. For example, we can define a predicate **valid/1**:

```

valid(F):-
    saturate([[f(F)]]).

```

The reader should experiment with this program, and attempt at least the first two of the following exercises.

**Exercise 4.2.1** Modify the code so that it handles the *nand* and *nor* connectives defined above.

**Exercise 4.2.2** Modify the code so that it handles the  $\leftrightarrow$  connective.

**Exercise 4.2.3** [hard] Reimplement propositional tableaux in a way that is more faithful to our hand-written tree based approach. That is, find a nice way of representing trees so that we don't need to duplicate branches when using disjunctive rules.

**Exercise 4.2.4** Experiment with different strategies in the tableaux program, by changing the order of the expansion rules.

**Exercise 4.2.5** [project] Add a pretty print predicate to our implementation of propositional tableaux, that shows the branches and the proof steps in a readable way. Test your printer on:  $(a \rightarrow \neg(b \wedge c)) \rightarrow ((a \rightarrow \neg b) \wedge (a \rightarrow \neg c))$ .

## 4.3 Equality Constraints

## 4.4 Theoretical Remarks

To conclude our discussion, we shall discuss four concepts that every reader should have at least a nodding acquaintance with: *soundness*, *completeness*, *termination* and *efficiency*. We won't pursue these topics in depth, nor will we prove any technical results. Rather, our aim is simply to give a clear account of what the concepts are, and how they relate to tableaux systems; for further details, the reader is advised to follow up the references cited in the Notes. Along the way, we shall clarify some points that may be bothering readers.

First of all, the tableaux system presented in this chapter is a *sound and complete* proof system for propositional inference. What does this mean?

As we remarked at the start of the chapter, although a syntactic proof method only *uses* syntactic information, it has to be *justifiable* in semantic terms. That is, when someone proposes some new proof method, we need guarantees that the proposal is semantically sensible.

The most fundamental property we demand of a proof system is that it be *sound*. Soundness is essentially a 'no garbage' demand: if the proof system proves some formula, then that formula must be valid. Sound proof systems are thus semantically justifiable in a very strong sense: they will *never* prove formulas which are falsifiable.

Our tableaux system is sound. That is, for any propositional formula  $\phi$ ,

$$\text{if } \vdash \phi \text{ then } \models \phi.$$

So tableaux proofs will never lead us astray—but this shouldn't really come as a surprise. After all, we developed our tableaux expansion rules by thinking in overtly semantic terms. For example, we asked "How do we go about making a conjunction true?" and gave the (obviously sensible) answer "By making both conjuncts true". Indeed, *all* our expansion rules reflect the semantic definitions of the connectives in an obvious way, so it is hardly surprising that they are 'semantically safe'. And in fact, one proves the soundness of the tableaux method simply by thinking a little more systematically about the consequences of the 'semantic safety' of the expansion rules. We won't spell the details out here, but they are not particularly difficult and we suggest that mathematically inclined readers try to pin down the required argument precisely.

What about completeness? This is a much stronger (and more interesting) demand: a complete proof system is one which is capable of proving *all* valid formula. That is, if  $\phi$  is any valid formula whatsoever, then it must be possible to give a proof of  $\phi$ .

Our tableaux system is complete. That is, for any propositional formula  $\phi$ ,

$$\text{If } \models \phi \text{ then } \vdash \phi.$$

Intuitively, no validity lies beyond the reach of the tableaux proof method: if a formula  $\phi$  is valid, then it is possible to expand the initial tableau  $F\phi$  to a closed tableau.<sup>1</sup> Note that because the tableaux method is both sound and complete we have that:

$$\vdash \phi \quad \text{iff} \quad \models \phi.$$

That is, we have a perfect match between the syntactic concept of tableaux-provability and the semantic concept of validity.

Proving that the tableaux method is complete is a non-trivial exercise which lies beyond the scope of this book; readers interested in the details should consult one of the references cited in the Notes. However, it *is* worth knowing that the key step of the completeness proof is to prove the following:

*If it is possible to expand an initial tableau  $F\phi$  to an open rule-saturated tableau, then one can falsify  $\phi$  by giving the atomic symbols the truth values stipulated on any of the open branches of such a tableau.*

This is worth knowing, because it allows us to dispel an issue that may be worrying some readers: how do we know that a formula *isn't* provable?

The problem is this. We defined  $\vdash \phi$  to mean that it is possible to extend the initial tableaux  $F\phi$  to a closed tableaux. Now, by changing the order we apply expansion rules, it may be possible to expand the initial tableau  $F\phi$  to many different rule-saturated tableau. This is worrying: perhaps some of these tableaux are open and others are closed! So, if we expand  $F\phi$  and obtain an open rule-saturated tableau, this doesn't seem to tell us much. Perhaps some other expansion would have led to a closed tableaux. Perhaps—what a horrible thought!—we have to check all possible tableaux expansions before we can safely conclude that  $\phi$  isn't provable.

In fact, we don't need to worry. For suppose some expansion of  $F\phi$  leads to an open rule-saturated tableau. Then, by the property just noted, it is possible to falsify  $\phi$ . It follows that no other expansion of  $F\phi$  can possibly lead to a closed rule-saturated tableaux. To see this, note that if there was such a closed rule-saturated tableau, this would mean that  $\phi$  was provable. By soundness, this would mean that  $\phi$  was valid—but this would contradict the fact that we can falsify  $\phi$ . In short, as soon as we succeed in expanding  $F\phi$  to an open rule-saturated tableau, it is safe to conclude that  $\phi$  is *not* provable.

Soundness and completeness are not the only desirable properties of proof systems. If one is interested in implementation, one wants to know something about a system's computational properties. For example, is the method guaranteed to *terminate* (or *halt* or *stop*) on all possible input formula? And how *efficient* is the method anyway?

---

<sup>1</sup>Incidentally, it is easy to give examples of tableaux systems that are sound but *not* complete—simply throw away expansion rules! For example, if we discard the rule  $F_{\neg}$ , we still have a *sound* tableaux system, but we don't have enough power left to prove all validities, as we can no longer have all the rules we need for coping with negated formulas.

The expansion process used by our propositional tableaux is guaranteed to halt on all possible input. To see why, note that every tableaux expansion rule takes a signed formula and returns a *finite* number of signed formulas (in fact, no rule returns more than four signed formula). Moreover, crucially, each of the formula returned contains fewer connectives than the input formula. Thus, as we never have to apply a rule to the same formula twice, after every expansion the collection of unexpanded formulas remains finite, and moreover, any new unexpanded formulas we obtain as a result of rule applications are *simpler*. Thus—no matter which sequence of expansions we choose to make—we will achieve rule-saturation after a finite number of steps. Termination is thus guaranteed. Making this argument really tight requires a little care, but the basic idea should be clear.

Are tableaux an efficient method of doing propositional inference? The honest answer is: *nobody knows*. In fact nobody knows if there is *any* proof method which can prove all valid formulas efficiently. Let's discuss this a little further.

For many formulas, tableaux fare better than other methods. To give an obvious example, suppose we tested the validity of the following formula using truth tables:

$$(q \rightarrow (r \vee (p \wedge \neg t \rightarrow \neg \neg s))) \vee \neg(q \rightarrow (r \vee (p \wedge \neg t \rightarrow \neg \neg s))).$$

The required truth table has 32 rows, which takes quite some time to fill out. The tableaux method, on the other hand, gets this example right in a single step. More generally, the tableaux method is obviously a fairly sensible, and by using a little common-sense when forming tableau (for example, applying as many conjunctive expansion rules as possible before applying disjunctive expansion rules) it is possible to give fairly concise proofs of typical validities.

Unfortunately, not all validities are 'typical'. It is possible to show that there are an infinite number of formulas which create terrible problems for the tableau method: any closed tableau formed by starting with one of these formulas contains a huge number of nodes. Finding such validities isn't easy. Devising them requires careful thought about which kind of formulas require heavy use of disjunctive rules. However, such validities are out there, thus although the tableau method looks better than the truth table method, the bottom line is that it is subject to the same kind of combinatorial explosions.

Now—as far as anybody knows—this isn't because tableaux is a poor proof method. In fact, nearly all the well known proof methods (such as resolution, natural deduction, and so on) have been shown to be subject to similar combinatorial explosions. There simply is no known proof method for propositional languages that avoids combinatorial explosion. In fact, it is widely conjectured that no such proof method exists. For further discussion of this point, consult the references cited in the Notes.

Let us sum up what we have learned in this section. As a proof method, the tableaux system introduced in this chapter is as well-behaved as one could reasonably hope for. It is semantically sensible, and moreover, strong enough to prove all valid formulas. Moreover, it is guaranteed to terminate on all possible input. On 'typical' formulas it seems reasonably

efficient—though the reader should be aware that there are (infinitely many) formulas which, if given as input, will give rise to tableaux that are too big to be practicably computed.

### Software Summary of Chapter 4

`propTabl.pl` The file that contains all the predicates for the implementation of our theorem prover. (page 237)

## Notes

Proof theory is a rich and fascinating subject. The reader can gain a good overview of various proof systems, and how they relate to each other, by consulting Sundholm 1983. Both signed and unsigned tableaux systems are discussed.

For tableaux systems, the classic source is Smullyan 1995; our discussion of signed tableaux is based on Smullyan's treatment. Good treatments of signed tableaux may be found in Fitting 1996 and Bell and Machover 1977. The reader interested in finding out how to prove the tableaux method complete will find all that is needed in these three books. Our implementation of propositional tableaux was influenced by the implementation of unsigned tableaux given in Fitting (1996). The reader will find it instructive to compare the two implementations. (Apart from anything else, it's a good idea to find out about what unsigned tableaux are and how they work.)

The analysis of the complexity of proof methods is an active field of research. Perhaps the best starting point is Urquhart 1995. This contains a good discussion of why the tableau method sometimes leads to combinatorial explosion. Another interesting (and very readable) paper is D'Agostino 1992, which shows that in certain cases the tableaux method performs *worse* than the truth table method.

Finally, although it takes us far from the concerns of the present book, it is worth noting that proof theory arguably has far deeper connections with natural language semantics than our discussion might suggest. There is an important tradition which claims that meaning shouldn't be explained in terms of truth conditions, but in terms of assertability conditions. (Roughly speaking, on this view the meaning of an utterance is the reason we have for holding it, not the situations in which it is true.) Semanticists in this tradition tend to regard proofs as the primary semantic objects. At first sight this may appear to be a rather strange view, but it has a lot to recommend it. A good introduction to this line of thought is Sundholm 1986. Moreover, as Ranta (1994) demonstrates, the approach is of relevance to computational semantics.

# Chapter 5

## First-Order Inference

In this chapter we extend our tableaux system to first-order languages. As promised, we do so by reducing first-order formulas to propositional ones. The resulting system is natural and easy for human beings to use. Unfortunately, as a candidate for automation it's awful: it makes use of an infinite space of possible substitutions that requires human insight to navigate.

So we rethink our strategy. Roughly speaking, we decide to delay the problem of finding good substitutions. Our plan is to use free variables to build up a set of constraints on substitutions, and then to hand over the problem of solving the constraints to a unification component. We discuss unification in detail, consider how to combine unification with the tableaux proof method, and implement a first-order theorem prover. We conclude with a discussion of the problems facing first-order theorem provers (and in particular, the problems raised by equality) and discuss alternative approaches.

### 5.1 First-Order Tableaux

We now extend the signed tableaux proof method to first-order languages. Conceptually, the extension is very simple. Our new tableaux rules will allow us get rid of quantifiers by substituting suitable terms for bound variables. In effect, they let us reduce first-order formulas to propositional ones.

What kinds of rules enable us to do this? Let's consider two examples. Suppose a tableau contains the signed formula  $T\forall x\text{KILLER}(x)$ , and suppose we are working with a first-order language containing the constants JULES and BUTCH and a 1-place function symbol FATHER. Then it should be legitimate to extend the tableau by adding on any of the following signed formulas:  $T\text{KILLER}(\text{JULES})$ ,  $T\text{KILLER}(\text{BUTCH})$ , and

$$T\text{KILLER}(\text{FATHER}(\text{FATHER}(\text{FATHER}(\text{JULES}))))).$$

(After all, if everyone is a killer, every term picks out a killer.) More generally, given any universal formula prefixed by the sign  $T$ , we should be free to throw away the universal quantifier, substitute any term for the newly freed variable in the matrix, prefix the result by  $T$ , and extend the tableau with the result.

Analogous tableaux extensions should be legitimate when we are told that an existential sentence is false. For example, suppose a tableau contains  $F\exists x\text{SHOOT}(\text{JULES},x)$ . Then it should be legitimate to deduce that  $F\text{SHOOT}(\text{JULES},\text{FATHER}(\text{JULES}))$ , and that  $F\text{SHOOT}(\text{JULES},\text{BUTCH})$ , and so on. (After all, if it's false that Jules shoots someone, then it's false that Jules shoots any person we care to name.)

Such examples lead us to formulate the following two tableaux rules,  $T_{\forall}$  and  $F_{\exists}$ :

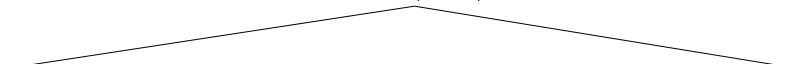

$$\frac{T\forall x\phi}{T\phi(\tau)} \qquad \frac{F\exists x\phi}{F\phi(\tau)}$$

Here  $\phi(\tau)$  denotes the result of replacing the variable bound by the quantifier by some closed term  $\tau$ . (Recall that a closed term is a term that does not contain any variables.) We call these two rules *universal rules*.

While both these rules are sound, and clearly trade on the semantic intuitions underlying the tableaux method, they differ from the propositional tableaux rules in important respects. First, each rule licenses as many tableaux extensions as there are closed terms in the language. In particular, if there are infinitely many closed terms in the language, each rule licenses infinitely many ways of extending a tableau. Second, in general we will have to apply a universal rule more than once to a particular occurrence of a signed formula. Here's a simple example. We shall show that

$$\forall x\text{DIE}(x) \rightarrow \text{DIE}(\text{MIA}) \wedge \text{DIE}(\text{ZED})$$

is a theorem.

1	$F(\forall x\text{DIE}(x) \rightarrow \text{DIE}(\text{MIA}) \wedge \text{DIE}(\text{ZED}))$	
2	$T\forall x\text{DIE}(x)$	1, $F_{\rightarrow}$
3	$F(\text{DIE}(\text{MIA}) \wedge \text{DIE}(\text{ZED}))$	1, $F_{\rightarrow}$
4	$T\text{DIE}(\text{MIA})$	2, $T_{\forall}$
5	$T\text{DIE}(\text{ZED})$	2, $T_{\forall}$
		
6	$F\text{DIE}(\text{MIA})$	3, $F_{\wedge}$
7	$F\text{DIE}(\text{ZED})$	3, $F_{\wedge}$

Note the way we had to apply  $T_{\forall}$  twice to line 2: once to get  $T\text{DIE}(\text{MIA})$ , and once to get  $T\text{DIE}(\text{ZED})$ . Thus we have lost one of the pleasant properties of propositional tableaux: it is no longer true that we are through with an occurrence of a signed formula once we've applied a rule to it.

Let's turn to the next issue. What sort of tableaux rules are needed to deal with signed formulas of the form  $T\exists x\phi$  or  $F\forall x\phi$ ? This is a more subtle matter. Suppose a tableau contains the signed formula  $T\exists x\text{KILLER}(x)$ . It is *not* legitimate on the basis of this information to deduce that  $T\text{KILLER}(\text{JULES})$ , or that  $T\text{KILLER}(\text{BUTCH})$ , or indeed to deduce that  $T\text{KILLER}(\text{CLOSED-TERM})$  for *any* closed term of the language we are working with. *Someone* is a killer—but we don't know who. So how are we to eliminate the quantifier?

Actually, the solution is straightforward: we invent a brand new name for the entity whose existence is asserted, and eliminate the quantifier by substituting this new name. Such brand new names are called *parameters*, and by using parameters we can deal with true existential statements, and false universal ones too. For example, if a tableau contains  $T\exists x\text{KILLER}(x)$ , we give this killer (whoever he or she is) a new name (that is, we choose a new parameter, say  $c$ ) and extend the tableau by asserting  $T\text{KILLER}(c)$ . Similarly, given the signed formula  $F\forall x\text{RELIGIOUS}(x)$ , we christen the unbeliever (whoever he or she is) with a new name (say  $c_8$ ) and extend the tableau by asserting  $F\text{RELIGIOUS}(c_8)$ .

Let's make these ideas precise. Suppose we are working in a first order language over some vocabulary  $V$ . Let  $\text{PAR}$  be a (countably infinite) set of new constant symbols, that is, constant symbols that *don't* belong to  $V$ . We'll call these new constant symbols parameters, and reserve the symbols  $c, c_1, c_2, \dots$ , and so on, for them. From now on, when we want to do tableaux proofs, we *won't* work in our original language (that is, the language built over the vocabulary  $V$ ). Rather we'll work in the first-order language whose vocabulary consists of all the original vocabulary  $V$ , and in addition, all the new constant symbols in  $\text{PAR}$ .

Given these ideas, it's easy to define the rules  $F_{\forall}$  and  $T_{\exists}$ :

$$\frac{F\forall x\phi}{F\phi(c)} \qquad \frac{T\exists x\phi}{T\phi(c)}$$

Here  $\phi(c)$  denotes the result of substituting a parameter  $c$  *that we haven't used so far in the tableau proof*, for the newly freed variable in the matrix. We call these two rules *existential rules*.

Two points about these rules must be grasped. First, when we use the existential rules, it is absolutely vital that we substitute parameters that haven't been used so far in the tableau construction. To see why, suppose a tableau contains both  $T\exists x\text{KILLER}(x)$  and  $T\exists x\text{RELIGIOUS}(x)$ . Suppose we first apply  $T_{\exists}$  to  $T\exists x\text{KILLER}(x)$  using the parameter  $c_5$  (which, let us suppose, hasn't been previously used) to name the killer. That is, we extend the tableau with  $T\text{KILLER}(c_5)$ . Now, if at some later stage we apply  $T_{\exists}$  to  $T\exists x\text{RELIGIOUS}(x)$ , it would be outrageous to re-use the parameter  $c_5$ . If we did this (that is, if we 'deduced' that  $T\text{RELIGIOUS}(c_5)$ ) we would in effect be claiming that there is a single individual (namely the one named by  $c_5$ ) who is both a killer and religious. This simply doesn't follow from the given information. All we know is that there is at least one

killer, and at least one religious person. They may well be different people, hence we need to assign each of them a fresh new name. In short, once we've used an existential rule to replace a quantifier by a parameter, that parameter becomes 'old', and cannot later be re-used.

There is a second important point that the reader should note: the definition of the existential rules has consequences for the universal rules. When carrying out first-order tableaux proofs we no longer work in the original first-order language, but in the original language enriched with an infinite collection PAR of new constants. Now, constant symbols—including parameters—are closed terms, so we should be free to substitute parameters when we use a universal rule. (In fact, it's *crucial* that we be able to do this, as the following example will make clear.) But this means that we will *always* have infinitely many choices when it comes to using a universal rule, even if the original language had no constants or function symbols at all.

Let's have a look at another example. We will show that

$$\exists x \forall y \text{SHOOT}(x, y) \rightarrow \forall y \exists x \text{SHOOT}(x, y)$$

is a theorem. (This is a rather pretty example. It's simple, but puts all four quantifier rules to work.)

1	$F(\exists x \forall y \text{SHOOT}(x, y) \rightarrow \forall y \exists x \text{SHOOT}(x, y))$	
2	$T \exists x \forall y \text{SHOOT}(x, y)$	1, $F_{\rightarrow}$
3	$F \forall y \exists x \text{SHOOT}(x, y)$	1, $F_{\rightarrow}$
4	$T \forall y \text{SHOOT}(c_1, y)$	2, $T_{\exists}$
5	$F \exists x \text{SHOOT}(x, c_2)$	3, $F_{\forall}$
6	$T \text{SHOOT}(c_1, c_2)$	4, $T_{\forall}$
7	$F \text{SHOOT}(c_1, c_2)$	5, $F_{\exists}$

The key point to notice about this proof is the way the existential and universal rules interact. In particular, note the way we used the existential rules to introduce the new parameters ( $c_1$  in line 4 and  $c_2$  in line 5) and then used the universal rules to make further use of these symbols. It should be clear from this example that it is vital that the universal rules have access to the parameters.

How efficient is this tableaux system? This is a question we must answer in two ways.

The first (and most fundamental) thing the reader should know is the following: the first-order tableaux system does *not* give rise to an algorithm for determining which first-order formulas are valid. An algorithm is a recipe which, when given an instance of a problem to solve, halts after a finite number of steps with the correct answer. *There is no algorithm at all for determining the validity of arbitrary first-order formulas.* That is, first-order validity is *undecidable*. It is certainly possible to implement syntactic proof systems (for example, tableaux systems) and we shall do in this chapter, but no implementation of any

system is guaranteed to terminate on all possible input. Incidentally, the tableaux system just described *is* (sound and) complete. That is, if a formula  $\phi$  is valid, then it is possible to construct a (finite) closed tableaux that has  $F\phi$  as its root node. Thus the proof system just described is a genuine syntactic analysis of the semantic concept of first-order validity, and indeed a rather natural one. However this analysis does not yield an algorithm for determining which first-order formulas are valid, for no such algorithm exists.

As there is no general computational solution to the problem, it is meaningless to speak of efficiency in an absolute sense, so let's restate the question in a more realistic way. Many first-order theorem provers are useful practical tools. Proof search won't always terminate, but they work well on wide ranges of input, and can be used as components of larger systems quite satisfactorily. So the question we should next pose is: how good is the tableaux system just described as a practical basis for automated first-order theorem proving? This question has a clear answer: *it's terrible*. Although our tableaux system is conceptually simple, it's a computational nightmare.

The heart of the problem lies with the universal rules. They offer us an infinite menu of substitutable terms. If  $T\forall x\phi$  belong to a tableau, then we are free to extend it by first adding  $\phi(c_1)$  then  $\phi(c_2)$  then  $\phi(c_3)$ , ..., and so. (We could have done this in the previous tableau, for example, starting at line 4.) Most such extensions will be completely pointless. In the examples given above, it was intuitively clear which substitutions were sensible; we used our sense of what was relevant to guide our choice of substitutions. Unfortunately, computers lack our intuitions. If we want a reasonably practical implementation, we need to find a method choosing substitutions that doesn't depend on human insight.

Here's what we shall do. First, we'll change the universal rules slightly: we'll never substitute closed terms, we'll *always* substitute free variables instead. In a sense, we are not going to make a real choice of substitutions at all—we are going to use free variables as 'dummies' that will enable us to delay making this decision. In this way, we will gradually build up a whole system of 'substitution equations', a set of constraints on variable values that contain a great deal of information about the terms in the tableau we are building. Crucially, there is an algorithm for solving such constraint sets, the famous *unification algorithm*. We will use unification to look for solutions to the constraints that lead to branch closure.

That's our strategy in outline. An awful lot of detail remains to be filled in. For a start, blending unification with tableaux is going to force us to rethink the existential rules, and there are many other details that will require careful attention. Nonetheless, unification is the key to further progress, so let's examine this concept in some detail.

## 5.2 Unification and Free Variable Tableaux

Unification is the process of carrying out substitutions on two terms so that they become identical. The reader who has made it this far will certainly have a informal idea of what substitutions are, and indeed, since we are working with Prolog, a good working knowledge of what unification involves in practice. However the Prolog version of unification is *not* suitable for theorem proving purposes. Given two terms, Prolog does not make the occurs check, rather it just rushes ahead and tries to unify them. This is fine (and certainly efficient) if the terms are unifiable, but it can lead to non-terminating computations if they are not. So we will need to think carefully about unification and how to implement it. Once we have done this, we will need to think about how to integrate unification into tableaux theorem proving. All in all, we have a lot of work to do, so let's get to start right away.

### Unification

Suppose we have chosen the first-order language we are going to work with. Then a *substitution* is a function that maps the set of variables to the terms of this language. We use the notation  $x\sigma$  (rather than  $\sigma(x)$ ) to denote the value of  $x$  under the substitution  $\sigma$ .

We are most interested in *finite substitutions*. These are substitutions which only assign new terms to a finite number of variables; the rest they leave alone. That is, if  $\sigma$  is a finite substitution, then for all but a finite number of variables,  $x\sigma = x$ .

The simplest finite substitution is the one which does not assign new terms to *any* of the variables. This substitution is called the *identity substitution*, and we denote it by  $\{\}$ . We also have a special notation for other finite substitutions, namely:

$$\{x_1/\tau_1, \dots, x_n/\tau_n\}.$$

Here  $x_1, \dots, x_n$  are distinct variables,  $\tau_1, \dots, \tau_n$  are terms, and  $\tau_i \neq x_i$  for any  $i$  from 1 to  $n$ . The notation  $x_i/\tau_i$  means that the variable  $x_i$  is mapped to  $\tau_i$ .

As we have defined them, substitutions only act on variables. In this section we will be exploring the effect of substitutions on arbitrary terms. Here's a recursive definition of this concept.

**Substitutions on Terms.** Let  $\sigma$  be a substitution and  $\tau$  a term. Then:

1. If  $\tau$  is a variable  $x$ , then  $\tau\sigma = x\sigma$ ;
2. If  $\tau$  is a constant, then  $\tau\sigma = \tau$ ;
3. If  $\tau$  has the form  $f(\tau_1, \dots, \tau_n)$ , then  $[f(\tau_1, \dots, \tau_n)]\sigma = f(\tau_1\sigma, \dots, \tau_n\sigma)$ . (Here  $f$  is an  $n$ -place function symbol.)

Actually, we need to extend the substitution concept even further, for in the following section we will want to apply substitutions to formulas, and indeed, to entire tableaux. So let's define these concepts right away. First a piece of notation. If  $\sigma$  is a substitution, then by  $\sigma_x$  we mean the substitution that is exactly like  $\sigma$  except that  $x\sigma_x = x$ . We can now recursively define  $\phi\sigma$ , the result of applying the substitution  $\sigma$  to the formula  $\phi$ .

### Substitutions on formulas.

1. If  $R(\tau_1, \dots, \tau_n)$  is an atomic formula, then  $[R(\tau_1, \dots, \tau_n)]\sigma$  is  $R(\tau_1\sigma, \dots, \tau_n\sigma)$ . (Here  $R$  is an  $n$ -place relation symbol.);
2.  $[\neg\phi]\sigma$  is  $\neg[\phi\sigma]$ ;
3.  $[\phi \wedge \psi]\sigma$ ,  $[\phi \vee \psi]\sigma$ , and  $[\phi \rightarrow \psi]\sigma$ , are  $[\phi\sigma] \wedge [\psi\sigma]$ ,  $[\phi\sigma] \vee [\psi\sigma]$ , and  $[\phi\sigma] \rightarrow [\psi\sigma]$  respectively;
4.  $[\forall x\phi]\sigma$  is  $\forall x[\phi\sigma_x]$ , and  $[\exists x\phi]\sigma$  is  $\exists x[\phi\sigma_x]$ .

**Substitutions on signed tableaux.** If  $\sigma$  is a substitution and  $\mathcal{T}$  is a signed tableau, then  $\mathcal{T}\sigma$  is the signed tableau obtained by replacing every signed formula of the form  $T\phi$  in  $\mathcal{T}$  by  $T[\phi\sigma]$ , and every signed formula of the form  $F\phi$  in  $\mathcal{T}$  by  $F[\phi\sigma]$ .

With these definitions out of the way, let us return to our main task: understanding unification.

Because substitutions are functions we can compose them in the usual way. That is, if  $\sigma_1$  and  $\sigma_2$  are substitutions, then we can define a new substitution  $\sigma_1\sigma_2$ , which we call the *composition* of  $\sigma_1$  and  $\sigma_2$ . For every variable  $x$ , we define  $x(\sigma_1\sigma_2)$  to be  $(x\sigma_1)\sigma_2$ . That is,  $\sigma_1\sigma_2$  first carries out the substitution  $\sigma_1$  and then carries out the substitution  $\sigma_2$ .

There is one more concept we need to discuss before we can define unification. Let's approach it via an example. Suppose we want to make the terms  $f(c,y,w)$  and  $f(x,y,g(z))$  identical (where  $c$  is a constant,  $w$ ,  $x$ ,  $y$ , and  $z$  are variables,  $f$  is a 3-place function symbol, and  $g$  is a 1-place function symbol). Let  $\sigma_1$  be the substitution  $\{x/c, w/g(z)\}$ . Applying  $\sigma_1$  to these terms has the desired result, for  $f(c,y,w)\sigma_1 = f(x,y,g(z))\sigma_1 = f(c,y,g(z))$ .

But there are other ways of making these terms identical. For example, let  $\sigma_2$  be the finite substitution  $\{x/c, w/g(z), y/h(u,x)\}$ . Applying  $\sigma_2$  to either term yields  $f(c,h(u,x),g(z))$ . Nonetheless, clearly  $\sigma_1$  is a more general solution to the problem:  $\sigma_2$  does too much work. For suppose we apply  $\sigma_1$  to some term. Then, if we want to (or need to) we are always free to later give  $y$  the value  $h(u,x)$ . To do so we need simply apply the substitution  $\{y/h(u,x)\}$ , and this two step process gives us the same effect we would have achieved by directly applying  $\sigma_2$ . But of course, we might not want to take this further step. (Perhaps mapping  $y$  to  $h(u,x)$  is incompatible with other substitutions we need to make.) If we use  $\sigma_2$  to solve the problem, we are overcommitting ourselves.

Such considerations motivate the following definition. A substitution  $\sigma_1$  is said to be *more general* than a substitution  $\sigma_2$  if and only if there is some substitution  $\theta$  such that  $\sigma_2 = \sigma_1\theta$ . That is,  $\sigma_1$  is more general than  $\sigma_2$  if we can get the effect of  $\sigma_2$  by first carrying out  $\sigma_1$  and then making a further substitution  $\theta$ . Thus, reverting to our motivating example,  $\{x/c, w/g(z)\}$  is more general than  $\{x/c, w/g(z), y/h(u, x)\}$  because there is a substitution  $\theta$  (namely  $\{y/h(u, x)\}$ ) such that  $\{x/c, w/g(z), y/h(u, x)\} = \{x/c, w/g(z)\}\theta$ .

Incidentally, note that under this (standard) definition of ‘more general than’, each substitution  $\sigma$  is more general than itself. This is because we can get the effect of  $\sigma$  by first carrying out  $\sigma$  and then carrying out the identity substitution  $\{\}$ . Thus the ‘more general than’ relation is reflexive. It is also transitive. That is, if  $\sigma_1$  is more general than  $\sigma_2$ , and  $\sigma_2$  is more general than  $\sigma_3$ , then  $\sigma_1$  is more general than  $\sigma_3$ . The reader may like to try proving this.

We are ready for the key definition.

**Unification.** Let  $\tau_1$  and  $\tau_2$  be terms. A substitution is a *unifier* for  $\tau_1$  and  $\tau_2$  if and only if  $\tau_1\sigma = \tau_2\sigma$ . Terms  $\tau_1$  and  $\tau_2$  are said to be *unifiable* if and only if they have a unifier. A substitution  $\sigma$  is a *most general unifier* (or *mgu*) for two terms if and only if it is unifier for these terms, and is more general than any other unifier.

Now we know what unification is—but what is involved in computing unifiers? Ideally, what we want is an algorithm which will take as input two terms and determine whether or not they are unifiable. If the terms are unifiable, it should return their unifier as output. If they are not unifiable, it should halt and tell us so.

Such algorithms exist. Let’s consider one of the more straightforward ones in some detail.

To appreciate what this algorithm does, we really need to think of terms as trees. For example, consider the term  $f(h(x), g(y, x, w))$ . Its parse tree—that is, the tree showing how it is built up out of sub-terms—looks like this:

When are two terms different? For our purposes, the following answer is the most useful: two terms are different if and only if their parse trees contain at least one *disagreement pair*. What’s a disagreement pair? Here’s an example.

Intuitively, the pair of terms  $(w, k(u, v))$  is a disagreement pair for these terms because they are distinct terms that occupy ‘corresponding places’ in the two parse-trees. What is meant by ‘corresponding places’? Simply the nodes that one reaches by following the same sequence of transitions from the root in the two trees. For example, if we follow the transition sequence ⟨second daughter, third daughter⟩ from the root of the first tree we arrive at the node labeled  $w$ , and if we follow the same transition sequence in the second tree we arrive at the node labeled  $k$ .

Disagreement pairs make terms different, thus unification algorithms should try to eliminate disagreement pairs. When are disagreement pairs eliminable, and how can they be eliminated?

First, suppose that two terms  $\tau_1$  and  $\tau_2$  are different because there a disagreement pair  $(d_1, d_2)$  such that *neither*  $d_1$  nor  $d_2$  is a variable. Then there is nothing we can do. No substitution can help us out. The terms  $\tau_1$  and  $\tau_2$  are not unifiable.

Now for the tricky question. Suppose that one of these terms ( $d_1$  say) is a variable. Are the two terms unifiable? The answer is ‘yes’, *provided that the variable  $d_1$  does not occur in  $d_2$* . Think about it. Suppose  $d_1$  is a variable, say  $x$ , and that  $x$  *doesn’t* occur in  $d_2$ . Then we can eliminate this disagreement pair very easily: we simply need to replace  $x$  by  $d_2$  (That is, we need simply perform the substitution  $\{x/d_2\}$ .) To give a concrete example, the disagreement pair  $(w, k(u, v))$  shown above is of this form. We eliminate it by replacing  $w$  by  $k(u, v)$ .

On the other hand, if  $d_1$  is a variable (say  $x$ ) and  $x$  *does* occur in  $d_2$ , then unification is impossible. For example, suppose that  $d_2$  is  $f(x)$ . Then, no matter what value we choose for  $x$ , we will *never* render these two terms identical—we’ll always have that extra function symbol  $f$  to reckon with.

Let’s make these observations a little more systematic. Suppose we have found a disagreement pair  $(d_1, d_2)$ . We will call this pair a *simple* disagreement pair if and only if at least one of the terms  $d_1$  or  $d_2$  is a variable that does not occur in the other. (It could happen, of course, that *both*  $d_1$  and  $d_2$  are variables that don’t occur in the other—for example if  $d_1 = x$  and  $d_2 = y$ . That’s fine. As long as there’s at least one we’re happy.) Simple disagreement pairs are the ones we can repair. We do so by carrying out what we shall call

the *relevant repair*. If  $d_1$  is a variable that does not occur in  $d_2$ , then the relevant repair is the substitution  $\{d_1/d_2\}$ . If  $d_2$  is a variable that does not occur in  $d_1$ , then the relevant repair is the substitution  $\{d_2/d_1\}$ . If both  $d_1$  and  $d_2$  are variables that don't occur in the other, then there are two substitutions that will repair the problem, namely  $\{d_1/d_2\}$  and  $\{d_2/d_1\}$ . We'll arbitrarily stipulate that in such cases the relevant repair is  $\{d_1/d_2\}$ .

On the other hand, if the disagreement pair we have found is *not* simple, there's nothing we can do. Either we have that neither  $d_1$  nor  $d_2$  is a variable, or one of them is a variable that occurs in the other term.

We now know which disagreement pairs are eliminable, and how to carry out the elimination. And this means, we are only one small step away from an algorithm for solving the unification problem. To unify two terms, simply try and eliminate *all* the disagreement pairs! This idea immediately suggests the following non-deterministic algorithm:

```

input terms  $\tau_1$  and  $\tau_2$ 
let  $\sigma := \{\}$ 
while  $\tau_1\sigma \neq \tau_2\sigma$ 
    choose a disagreement pair  $(d_1, d_2)$  for  $\tau_1\sigma, \tau_2\sigma$ 
    if  $(d_1, d_2)$  is not simple then
        write  $\tau_1$  and  $\tau_2$  are not unifiable and HALT
    else
        let  $\sigma := \sigma \cup \rho$ , where  $\rho$  is the relevant repair
    endif
endwhile

```

This is a genuine computational solution of the unification problem. No matter which two terms it is given as input, it will halt after finitely many steps. When it halts, it will either have told us that the terms are not unifiable (and if it says this, it's right!) or it will have found out how to build the mgu of the two terms. These claims are not obvious; they require proof. The reader interested in finding out more should consult the references cited in the Notes.

In fact, the algorithm has one additional property: the mgus it produces are *idempotent*. That is, if  $\sigma$  is an mgu produced by this algorithm, then  $\sigma\sigma = \sigma$ . Why on earth is such an abstract looking property interesting? The answer is: idempotent mgus provide us with an easy way of solving the *simultaneous unification problem*, and actually this problem will be important when working with tableaux.

We will be using unification to try and close tableaux branches. That is, we will look for branches containing pairs of atomic formula  $T(R(\tau_1, \dots, \tau_n))$  and  $F(R(\tau'_1, \dots, \tau'_n))$ . If we can find a substitution  $\sigma$  that makes  $\tau_1$  identical to  $\tau'_1$ , and  $\dots$ ,  $\tau_n$  identical to  $\tau'_n$ , then by applying  $\sigma$  we obtain a branch containing contradictory formula, that is, a closed branch. Thus we need to solve the problem of finding a single substitution that makes  $n$  pairs of terms identical; this is called the simultaneous unification problem.

Now, this problem may look harder than the ordinary unification problem, but actually it's not. It can be solved as follows. To find a substitution that identifies  $n$  pairs of terms, first find an *idempotent* mgu  $\sigma_1$  for  $\tau_1$  and  $\tau'_1$ . We can do this using the above algorithm. Next, find an *idempotent* mgu  $\sigma_2$  for  $\tau_2\sigma_1$  and  $\tau'_2\sigma_1$ . Again we can do this using the above algorithm. Next, find an *idempotent* mgu  $\sigma_3$  for  $\tau_3\sigma_1\sigma_2$  and  $\tau'_3\sigma_1\sigma_2 \dots$ . In fact, all we need to do is keep 'chaining together' the solutions to each individual pair. The substitution  $\sigma = \sigma_1\sigma_2 \dots \sigma_{n-1}\sigma_n$  that is obtained in this way is a simultaneous mgu for the  $n$  pairs of terms. For this 'chaining together' method to work, the substitutions constructed at each step must be idempotent, and as the above algorithm yields idempotent mgus, it really does deliver everything we shall need for tableaux theorem proving.

The basic concepts should now be clear, so let's turn to a more practical issue: how can we use Prolog to unify terms? Now, we could approach this problem from scratch. However (as the reader is undoubtedly aware) one of the main mechanisms underlying Prolog is a form of unification. Perhaps we can use Prolog's in-built unification mechanism directly, or adapt it straightforwardly, to perform the term unifications we require? This certainly seems a sensible choice of strategy. Let's see what it involves.

The way Prolog performs unification is reasonably close to the above algorithm. There are two main differences. First, the algorithm given above is non-deterministic, whereas Prolog's in-built mechanism for unifying terms is deterministic. Clearly this is not a difference that need concern us. The second difference, however, is important. In the interests of efficiency, Prolog does not bother making the 'occurs check'. That is, given a disagreement pair  $(d_1, d_2)$ , one of which is a variable, Prolog does *not* check whether this variable occurs in the other term, but will go straight ahead and attempt to carry out what it thinks the required repair is. This leads it to attempt to unify terms that aren't unifiable, and thus to stack overflows and other undesirable behaviour.

Now, we are interested in using unification as part of a first-order theorem prover. We really need to know whether or not two terms are unifiable, and we certainly *don't* want Prolog to mess things up with its 'Hey, just go for it!' behaviour. Can Prolog be tamed? That is, can we make use of its in-built unification mechanism, but modify it so that makes an occurs check? The answer is 'yes'. The following code, adapted from Chapter 10 of Sterling and Shapiro (Sterling and Shapiro 1986), does precisely this.

The main predicate `unify` uses the in-built unification predicate `=` to carry out the required unifications, but carefully inserts an occurs check (via the `notOccursIn/2` predicate) where required.

```

unify(X,Y):-
    var(X), var(Y), X=Y.

unify(X,Y):-
    var(X), nonvar(Y), notOccursIn(X,Y), X=Y.

unify(X,Y):-
    var(Y), nonvar(X), notOccursIn(Y,X), X=Y.

unify(X,Y):-
    nonvar(X), nonvar(Y), atomic(X), atomic(Y), X=Y.

unify(X,Y):-
    nonvar(X), nonvar(Y), compound(X), compound(Y), termUnify(X,Y).

```

So how is `notOccursIn/2` to be defined? Well, if the term is a variable, then the key idea is to make use of the in-built Prolog metalogical predicate `\==` (Recall that query `X \== Y` succeeds if and only if `X` and `Y` are not identical.) This is coded in the first clause. The second clause handles the case where the term is atomic (we don't have to do anything else in such a case), and the third clause takes care of the case where the term is complex.

```

notOccursIn(X,Term):-
    var(Term), X \== Term.

notOccursIn(_,Term):-
    nonvar(Term), atomic(Term).

notOccursIn(X,Term):-
    nonvar(Term), compound(Term),
    functor(Term,_,Arity), notOccursInComplexTerm(Arity,X,Term).

```

The `notOccursInComplexTerm` predicate recursively checks whether the variable `X` does not occur in either of the arguments of the complex term `Term`, making use of the `notOccursIn` predicate as you would have expected.

```

notOccursInComplexTerm(N,X,Y):-
    N > 0, arg(N,Y,Arg), notOccursIn(X,Arg),
    M is N - 1, notOccursInComplexTerm(M,X,Y).

notOccursInComplexTerm(0,_,_).

```

All that remains is to define the predicates which were used in the definition of `unify/2`. The predicate `termUnify/2` first checks if the terms have the same functor symbols and arity, and then uses `unifyArgs/3` to unify their arguments.

```
termUnify(X,Y):-
    functor(X,Functor,Arity), functor(Y,Functor,Arity),
    unifyArgs(Arity,X,Y).

unifyArgs(N,X,Y):-
    N > 0, M is N - 1,
    arg(N,X,ArgX), arg(N,Y,ArgY),
    unify(ArgX,ArgY), unifyArgs(M,X,Y).

unifyArgs(0,_,_).
```

## Free variable Tableaux

Let's see how we can use unification to define a more computationally realistic signed tableaux proof system.

As we discussed earlier, the problem with our first attempt at a first-order tableaux system lay with the universal rules. Because they offered us too many ways of making substitutions (in fact, infinitely many) human insight was required to find proofs. By substituting free variables, and gradually building up a system of constraints which we will solve using unification, we hope to bypass the need for human insight. Let's work through this idea in detail, and see where it leads. As a first step, here are our new universal rules:

$$\frac{T\forall x\phi}{T\phi(v)} \qquad \frac{F\exists x\phi}{F\phi(v)}$$

Here  $\phi(v)$  denotes the result of replacing all instances of the variable that the quantifier bound by a new variable  $v$  that does not occur bound anywhere in the tableau. (This restriction is simply to prevent any 'accidental bindings' taking place. In fact, every time we apply these rules, we're going to substitute a previously unused variable.)

So far so good—but a moment's thought will convince the reader that our new strategy could lead to serious problems with the existential rules. Recall that the basic idea behind the existential rules was to invent a brand new name for the entity asserted to exist (we called these new names 'parameters') and to eliminate the quantifier by substituting these parameters. Unification threatens to undercut this strategy completely: the substitutions it makes may undo all our careful choices of new names! In short, we seem to be in a dilemma. The use of free variables in the universal rules is essentially a 'delaying' device;

we don't want to make a real choices of what to substitute, we want unification to sort it all out for us. But if we delay in this way, how can we guarantee that unification will respect the 'new names' concept that is crucial to the existential rules?

A very clever—and very simple—idea allows us a way round this problem. We are going to substitute *structured* terms when we use the existential rules; the term structure itself will ensure that unification cannot spoil anything. To be more precise, we are to use what are known as *Skolem terms*. Without further ado, here are the new existential rules:

$$\frac{F\forall x\phi}{F\phi(s(x_1, \dots, x_n))} \qquad \frac{T\exists x\phi}{T\phi(s(x_1, \dots, x_n))}$$

Here  $s$  is a new *Skolem function symbol*, and  $x_1, \dots, x_n$  are all the free variables in  $\phi$ . (If there are no free variables,  $s$  is a new *Skolem constant*.) What does this mean, and why does it work?

The basic idea is a straightforward generalisation of what we did earlier with parameters. Once again, instead of working with the first-order language built over the original vocabulary  $V$ , we are going to choose a set of new symbols  $SKO$  consisting of a countably infinite set of Skolem constants (these are essentially the same as our earlier parameters) and for every natural number  $n$  a countably infinite set of Skolem function symbols of arity  $n$ . When carrying out tableaux proofs, we won't work in the original first-order language, but first-order language whose vocabulary consists of all the original vocabulary  $V$  plus all the new symbols in  $SKO$ .

The symbols in  $SKO$  enable us to manufacture new names. Crucially, however, because we now have Skolem *function* symbols at our disposal, we can do something that we couldn't do with parameters: we can 'build in newness' in a way that will survive the unification operation! Look at the term the existential rules demands we substitute:  $s(x_1, \dots, x_n)$ , where  $x_1, \dots, x_n$  are all the free variables in  $\phi$ . Now recall our discussion of the occurs check. Quite simply,  $s(x_1, \dots, x_n)$  *cannot* unify with any of  $x_1, \dots, x_n$ . Our new 'Skolem structured' term really will be new.

"Oh really?" the skeptical reader will demand. "The basic idea is clear, but the restriction simply isn't strong enough! When we used parameters, we had to pick a parameter that was brand new *to the entire tableau*. But look: the above rule only ensures that the new structured name won't unify with any of the free variables in  $\phi$  itself! We should really insist that the new instantiated name be  $s(x_1, \dots, x_n)$ , where  $x_1, \dots, x_n$  are all the free variables *in the entire tableau*!"

This is an intelligent observation. Our skeptical reader is certainly thinking about the rule in the right way. The suggestion is sensible: instantiations certainly *could* be carried out that way. Nonetheless, we don't *have* to (and for this we should be grateful, since it means we can substitute smaller Skolem terms). The simpler rule stated above is sound. This is not obvious, and for a proof (and further discussion) of this matter the reader should

consult the sources cited in the Notes.<sup>1</sup>

We now have the new quantifier rules we need. Only one task remains: bringing unification into play.

We want unification to be the ‘intelligence’ guiding the proof search. We’re going to use our quantifier rules essentially ‘blindly’: we’re simply going to build up a set of constraints and hope that unification can do something useful with them. In particular, we hope that unification will be able to close branches for us. How could it do this for us? Let’s consider an example. We shall redo our proof of

$$\exists x \forall y \text{SHOOT}(x, y) \rightarrow \forall y \exists x \text{SHOOT}(x, y)$$

using our new quantifier rules and unification. Here are the first 7 steps of the construction.

1	$F(\exists x \forall y \text{SHOOT}(x, y) \rightarrow \forall y \exists x \text{SHOOT}(x, y))$	
2	$T \exists x \forall y \text{SHOOT}(x, y)$	1, $F_{\rightarrow}$
3	$F \forall y \exists x \text{SHOOT}(x, y)$	1, $F_{\rightarrow}$
4	$T \forall y \text{SHOOT}(s_1, y)$	2, $T_{\exists}$
5	$F \exists x \text{SHOOT}(x, s_2)$	3, $F_{\forall}$
6	$T \text{SHOOT}(s_1, v_1)$	4, $T_{\forall}$
7	$F \text{SHOOT}(v_2, s_2)$	5, $F_{\exists}$

The first 5 lines are essentially identical with the previous version, save that we have used the Skolem constants  $s_1$  and  $s_2$  (rather than the parameters  $c_1$  and  $c_2$ ) in lines 4 and 5. (Note that we don’t need to use Skolem functions as neither formula contains free variables.) The real difference occurs in lines 6 and 7. In both lines we have ‘blindly’ instantiated in new variables, namely  $v_1$  and  $v_2$ . So we don’t (yet) have closure.

But closure is easy to get. Consider the substitution  $\{v_1/s_2, v_2/s_1\}$ . If we apply this to the tableau (recall that we defined the concept of applying a substitution to a tableau in the previous section) we get the following tableau:

1	$F(\exists x \forall y \text{SHOOT}(x, y) \rightarrow \forall y \exists x \text{SHOOT}(x, y))$	
2	$T \exists x \forall y \text{SHOOT}(x, y)$	1, $F_{\rightarrow}$
3	$F \forall y \exists x \text{SHOOT}(x, y)$	1, $F_{\rightarrow}$
4	$T \forall y \text{SHOOT}(s_1, y)$	2, $T_{\exists}$
5	$F \exists x \text{SHOOT}(x, s_2)$	3, $F_{\forall}$
6	$T \text{SHOOT}(s_1, s_2)$	4, $T_{\forall}$
7	$F \text{SHOOT}(s_1, s_2)$	5, $F_{\exists}$

This tableau *is* closed.

---

<sup>1</sup>Readers with some background in logic should try proving it themselves. Once you’ve been alerted to the fact that the simpler rule is sound, it’s not that difficult to work out why. (Like so many things in logic and computer science, it’s spotting the simplification in the first place that’s tricky.)

This example motivates the addition of the following *Atomic MGU Closure Rule*:

Suppose that  $\mathcal{T}$  is a tableau formed from some initial tableau  $\mathcal{I}$ , and that some branch of  $\mathcal{T}$  contains a pair of atomic formulas of the form  $T(R(\tau_1, \dots, \tau_n))$  and  $F(R(\tau'_1, \dots, \tau'_n))$ . Then  $\mathcal{T}\sigma$  is also a tableau formed from the initial tableau  $\mathcal{I}$ , where  $\sigma$  is a simultaneous mgu of  $\tau_1$  and  $\tau'_1, \dots$ , and  $\tau_n$  and  $\tau'_n$ .

This rule is rather different from the other rules we've seen: it's not an extension rule, rather it's a transformation rule. It tells us that if we have tableau formed from an initial set  $\mathcal{I}$ , and we transform it by applying a substitution having certain properties, we obtain another tableau for the same initial set.

The basic idea guiding the choice of transformation should be clear: we want to apply substitutions that could lead to branch closure. One point, however, may be puzzling. Obviously we are interested in pairs of formulas of the form  $T\phi$  and  $F\phi$ , but why have we restricted our attention to *atomic* formulas? The answer is: *simplicity*. In fact we could have formulated a more general rule, but if we did so we would have to state it carefully (we would need to avoid 'accidental capture' of variables) and checking for accidental capture would be computationally expensive. By restricting our attention to atomic formulas we avoid these difficulties.

And that's our free variable tableaux proof system. Frankly, it's not nearly as nice as our previous system if one wants to prove things by hand—playing with Skolem functions swiftly get unwieldy, and thinking in terms of unification is cumbersome. But it wasn't designed with the needs of humans in mind, it was designed for automation. And, as we shall now see, for this purpose it is really rather good.

### 5.3 Implementing Free Variable Tableaux

We shall now present an implementation of the free variable signed tableaux proof system. The implementation is an extension of the propositional tableaux implementation—but it can't be described as a straightforward extension. While the basic ideas underlying signed free variable tableaux make it possible to devise practical implementations, there is more detail to take care of than in the propositional case. Moreover, the fact remains that first-order logic is undecidable, so the implementation has to defuse the (very real) threat of non-terminating tableaux constructions, and this requires a little care.

Our implementation draws on the Fitting (Fitting 1996) implementation of free variable unsigned propositional tableaux. Roughly speaking, we take our signed propositional tableaux implementation as the starting point, and extend it to a first-order system by adopting many of Fitting's design choices. For further information, see the Notes.

Before examining the main body of the code, let's take a quick look at the main supporting routines we shall use. Obviously we need predicates to handle substitution. The workhorse is the `substitute` predicate (supplied in `comsemPredicates.pl`), which we examined in Section 2.4. Recall that the `substitute/4` predicate takes a term, a variable, and a formula as its first three arguments, and returns in its fourth argument the result of substituting the term for each free occurrence of the variable in the formula. With it predicate at our disposal, it is straightforward to define what we mean by instances of quantified formulas:

```
instance(t(forall(X,F)),Term,t(NewF)):-
    substitute(Term,X,F,NewF).

instance(f(exists(X,F)),Term,f(NewF)):-
    substitute(Term,X,F,NewF).

instance(t(exists(X,F)),Term,t(NewF)):-
    substitute(Term,X,F,NewF).

instance(f(forall(X,F)),Term,f(NewF)):-
    substitute(Term,X,F,NewF).
```

To handle the existential rule correctly, we need to be able generate new Skolem function symbols on demand. The following predicate does this. (The predicates it calls may be found in `comsemPredicates.pl`.)

```
skolemFunction(VarList,SkolemTerm) :-
    newFunctionCounter(N),
    compose(SkolemTerm,fun,[N|VarList]).
```

We shall also need to know what free variables a formula contains. We associate this information explicitly with each formula. The following predicate does this.

```
notatedFormula(n(Free,Formula),Free,Formula).
```

We are now ready to discuss the main code. As in the propositional case, the outermost predicate is called `saturate`. This recursively attempts to rule-saturate the input tableau with the aid of the `expand` predicate. Moreover, as in the propositional case, the base clause of `saturate` tests for closure via a predicate called `closed`.

But there is an important difference. The first-order version `saturate` has a second argument, a number called `Qdepth` (which can be read as 'quantification depth'). This number is the maximum number of times that we are allowed to apply universal rules in the course of constructing a tableau. This is the mechanism which wards off the threat of non-terminating tableaux constructions.

```

saturate(Tableau,_) :-
    closed(Tableau).

saturate(OldTableau,Qdepth) :-
    expand(OldTableau,Qdepth,NewTableau,NewQdepth),!,
    saturate(NewTableau,NewQdepth).

```

The `closed/1` predicate tests for branch closure using unification. It attempts to find a pair of signed formulas of the form  $t(X)$  and  $f(X)$ , and then uses the `unify` predicate discussed in the previous section to test for branch closure.

```

closed([]).

closed([Branch|Rest]) :-
    member(NotatedOne,Branch),
    notatedFormula(NotatedOne,_,t(X)),
    member(NotatedTwo,Branch),
    notatedFormula(NotatedTwo,_,f(Y)),
    unify(X,Y),
    closed(Rest).

```

Like its propositional cousin, the `expand/4` predicate is a high level organisational predicate which works its way recursively through the branches of the input tableau, and tries to apply the various kinds of expansion. Its two extra arguments keep track of the input and output quantification depths. Quantification depth is unaffected by all expansions save universal expansions. Each universal expansion ‘uses up’ one of our predetermined quota of expansions and thus decrease the quantification depth by 1.

In addition, `expand/4` performs a more interesting task. Note the use of `append` (in the clause handling universal expansions) to glue the new branch back onto the *end* of the tableau. Why do this? Essentially, it’s an attempt to ensure that our predetermined quota of universal expansions are ‘spread around fairly’. It would be rather silly to use up our entire quota on a single branch. By using `append` to ‘rotate’ the branches on the tableau, we ensure that every branch receives its fair share of universal expansions.

```

expand([Branch|Tableau],QD,[NewBranch|Tableau],QD) :-
    unaryExpansion(Branch,NewBranch).

expand([Branch|Tableau],QD,[NewBranch|Tableau],QD) :-
    conjunctiveExpansion(Branch,NewBranch).

expand([Branch|Tableau],QD,[NewBranch|Tableau],QD) :-

```

```

    existentialExpansion(Branch,NewBranch).

expand([Branch|Tableau],OldQD,NewTableau,NewQD):-
    universalExpansion(Branch,OldQD,NewBranch,NewQD),
    append(Tableau,[NewBranch],NewTableau).

expand([Branch|Tableau],QD,[NewBranch1,NewBranch2|Tableau],QD):-
    disjunctiveExpansion(Branch,NewBranch1,NewBranch2).

expand([Branch|Rest],OldQD,[Branch|Newrest],NewQD):-
    expand(Rest,OldQD,Newrest,NewQD).

```

Now for the predicates that actually carry out the expansions. The expansion predicates for unary, conjunctive, and disjunctive formulas are essentially the same as in the propositional case. The only difference is that we have to translate a notated formula into a signed formula to calculate its components, and then translate the components back again into notated components.

```

unaryExpansion(Branch,[NotatedComponent|Temp]) :-
    unary(SignedFormula,Component),
    notatedFormula(NotatedFormula,Free,SignedFormula),
    removeFirst(NotatedFormula,Branch,Temp),
    notatedFormula(NotatedComponent,Free,Component).

conjunctiveExpansion(Branch,[NotatedComp1,NotatedComp2|Temp]) :-
    conjunctive(SignedFormula,Comp1,Comp2),
    notatedFormula(NotatedFormula,Free,SignedFormula),
    removeFirst(NotatedFormula,Branch,Temp),
    notatedFormula(NotatedComp1,Free,Comp1),
    notatedFormula(NotatedComp2,Free,Comp2).

disjunctiveExpansion(Branch,[NotComp1|Temp],[NotComp2|Temp]) :-
    disjunctive(SignedFormula,Comp1,Comp2),
    notatedFormula(NotatedFormula,Free,SignedFormula),
    removeFirst(NotatedFormula,Branch,Temp),
    notatedFormula(NotComp1,Free,Comp1),
    notatedFormula(NotComp2,Free,Comp2).

```

The most interesting are `existentialExpansion/2` and `universalExpansion/4`. Note the use of `skolemFunction/2` to instantiate a new Skolem term in `existentialExpansion`. In `universalExpansion/4`, note that quantification depth is decremented, a new variable `V` is ‘blindly’ instantiated, and then—on the very last line—note the way `append` is used

to replace the universal formula we have been working with back on *end* the branch. Why do this? Well, we need to replace the formula because (as we have already discussed) we will often have to re-use universal formulas. But then it makes very good sense to replace the formula at the *end* of the branch. If we leave it where it is, we run the risk of using up our entire quota of universal rule applications on this one formula. It is far more sensible to ensure fairness by ‘rotating’ the universal formulas on the branch, much as we rotated the branches of the tableau earlier.

```

existentialExpansion(Branch, [NotatedInstance|Temp]) :-
    notatedFormula(NotatedFormula, Free, SignedFormula),
    existential(SignedFormula),
    removeFirst(NotatedFormula, Branch, Temp),
    skolemFunction(Free, Term),
    instance(SignedFormula, Term, Instance),
    notatedFormula(NotatedInstance, Free, Instance).

universalExpansion(Branch, OldQD, NewBranch, NewQD) :-
    OldQD > 0, NewQD is OldQD - 1,
    member(NotatedFormula, Branch),
    notatedFormula(NotatedFormula, Free, SignedFormula),
    universal(SignedFormula),
    removeFirst(NotatedFormula, Branch, Temp),
    instance(SignedFormula, V, Instance),
    notatedFormula(NotatedInstance, [V|Free], Instance),
    append([NotatedInstance|Temp], [NotatedFormula], NewBranch).

```

There is one tricky point in the definition of the universal expansion predicate: the use of `member/2` in the very first lines of it. At first sight this line of code seems superfluous (note that we don’t have it in the other expansion predicates). However, if we leave out the call to `member/2`, `universal/1` will pick the first of the two universal formulas format, adds it component to the beginning of the branch, and puts the universal formula back at the end of the branch (via `removeFirst` and `append`). In a case where there are two different universal formulas on a branch, one of them will never be touched, and the Q-depth will be wasted on the other. Adding `member` at the beginning of the clause overcomes this problem.

Now it only remains to spell out what kinds of signed formula we are working with.

```

conjunctive(t(X & Y), t(X), t(Y)).
conjunctive(f(X v Y), f(X), f(Y)).
conjunctive(f(X > Y), t(X), f(Y)).

```

```

disjunctive(f(X & Y),f(X),f(Y)).
disjunctive(t(X v Y),t(X),t(Y)).
disjunctive(t(X > Y),f(X),t(Y)).

unary(t(~X),f(X)).
unary(f(~X),t(X)).

universal(t(forall(_,_))).
universal(f(exists(_,_))).

existential(t(exists(_,_))).
existential(f(forall(_,_))).

```

As with the propositional implementation, it's nice to have a driver that translates the formula into a notated, signed formula, and calls the `saturate` predicate. We call this predicate `valid/2`, as in our implementation for propositional tableaux. Its second additional argument is the value of Q-depth.

```

valid(X,Qdepth):-
    notatedFormula(NotatedFormula,[],f(X)),
    saturate([[NotatedFormula]],Qdepth).

```

We conclude with a warning. Remember that this program can only construct those tableaux which require fewer applications of the universal rules than the user-imposed `Qdepth` limit. Thus if checking a formula with `valid/2` fails, this most emphatically does *not* mean “Not a first-order tableau theorem”! The formula in question may well be a tableaux theorem—perhaps we just set `Qdepth` to too small a value for a proof to be found. (Incidentally, while trying this program out on the kinds of formula found in introductory logic books, we usually had `Qdepth` set to 25.) On the other hand, if the program tells us that  $\phi$  is a first-order tableaux theorem, this is not open to question. If a closed tableau has been formed from the initial tableau  $F\phi$ , then  $\phi$  is provable, and that's that.

**Exercise 5.3.1** Add a pretty print predicate to our implementation of first-order tableaux, that shows the branches and the proof steps in a readable way.

## 5.4 Off-the-shelf Inference Tools

To be provided....

## Software Summary of Chapter 5

`freeVarTabl.pl` The file that contains the code for free variable tableaux, using a number of ideas from Melvin Fitting's implementation for first-order logic. (page 240)

`callTheoremProver.pl` The Prolog-interface to the theorem prover Otter. (page 245)

`callModelBuilder.pl` The Prolog-interface to the model builder Mace. (page 246)

`fol2otter.pl` Translates a formula in Otter syntax to standard output. (page 247)

## Notes

The human-oriented tableaux system presented at the start of the chapter is a typical first-order signed tableaux system; essentially identical systems may be found in Smullyan 1995 and Sundholm 1983, and Bell and Machover 1977, Fitting 1996, Smullyan 1995, Sundholm 1983 discuss it's unsigned counterpart. Incidentally, we really meant what we said in the text. If you want to do tableaux proofs by hand, use *this* system; its free-variable cousin wasn't designed for people but for computers.

Unification and the unification algorithm were introduced in Robinson 1965 for the purposes of automated theorem proving. The algorithm discussed in the text is essentially Robinson's original. The literature unification is now huge, and a wide variety of unification algorithms have been investigated. We suggest that the reader who wants to know more try Fitting 1996 or Apt 1995. Fitting's discussion is very clear, and should be accessible to most readers of this book. Apt's discussion is more advanced, but still very approachable. He gives a nice account of idempotent substitutions, and analyses three unification algorithms, including the non-deterministic Robinson algorithm presented here. This is also a good source for further pointers to the literature.

The free variable proof system presented in the text is a signed version of the unsigned free variable tableaux system presented in Fitting 1996, and the reader interested in learning more about the soundness and completeness of the system is advised to start there (perhaps using Smullyan as a backup). Any skeptical readers still worried by the soundness of the existential rule should consult Hähnle and Schmitt (1994). A useful general source is Gallier (1986). This is a detailed introduction to the theory of first-order theorem proving that covers tableaux, unification and much else besides.

To extend our propositional implementation to first-order logic, we have by and large

followed the Fitting (1996) strategy for unsigned tableaux. In particular, our use of `Qdepth`, and the subsequent decision to use `append` to ‘rotate’ branches of tableaux, and universal signed formulas on branches, follows Fitting. (Incidentally, this technique has a name. We are essentially treating both tableaux and branches as *priority queues*. The idea of doing this in tableaux proofs dates back to Smullyan (1995)). The implementation of `skolemFunction` is taken from Fitting, and the `notatedFormula` predicate is Fitting’s `notation` and `fmla` predicates rolled into one.

# Chapter 6

## Putting It All Together

We now have some answers to the two questions with which these notes began.

1. *We can build first-order representations in a compositional way for simple natural language expressions. (Moreover, we are able to do in a way that takes scope ambiguities into account.)*
2. *We have automated the process of performing reasoning with (equality free) first-order representations.*

Along the way, we've developed a number of useful tools. Now it's time to have a little fun and bring the various bits and pieces together. As we shall see, by 'plugging together' our lambda calculus, quantifier storage, model checking and theorem proving programs we are able to define simple question handling and argumentation predicates. All that's involved is some minor extensions to our DCGs, and a few simple driver definitions.

### 6.1 Natural Language Questions

From Chapter 2 we know how to compositionally build semantic representations for simple expressions of English, and from Chapter 1 we know how to evaluate first-order formulas in well-named models. Now, well-named models are just (rather primitive) databases. Let us extend our grammar coverage so that we can pose simple natural language database queries to them.

First we introduce some new syntactic categories: `q` for questions, and `wh` for wh-phrases. Second, we define a DCG rule that makes a question out of a wh-phrase and a verb phrase:

```
q(WH@VP)--> wh(WH), vp2(VP).
```

(Note that this rule is the essentially the same as the rule that makes sentences out of noun phrases and verb phrases.) The third step is to add the rules for the wh-phrases:

```
wh(lambda(P,lambda(X,P@X)))--> [who] .
```

```
wh(lambda(P,lambda(X,(N@X) & (P@X))))--> [which] , n2(N) .
```

With these entries we can handle questions like ‘Who is a customer?’ or ‘Which robber loves Honey Bunny?’. The semantic representations that are derived for questions are lambda expressions, for example:

```
?- q(Sem,[who,is,a,customer],[ ]).
```

```
Sem = lambda(X,customer(X))
```

The final step is to write a driver that translates a question into a lambda expression, feeds it to an example model, and returns the answer. (The example models we use here are those of Chapter 1.) The driver can be coded as follows:

```
query(Example):-
    readLine(Question),
    q(Q,Question,[ ]),
    betaConvert(Q,lambda(Answer,Sem)),
    evaluate(Sem,Example),
    write(Answer), nl, fail.
```

With `readLine/1` Prolog waits for the user to enter a question. The user’s input is given to the DCG, which returns the representation for the question entered. After conversion, we require the semantic representation being of the form `lambda(Answer,Sem)`, that is, a question.

Now, the way we designed the treatment of questions, `Sem` will contain a free occurrence of the variable `Answer`. Feeding the formula `Sem` to the evaluation predicate, after making it a sentence, generates all possible (and correct) assignments for `Answer`, as we have learned from Chapter 1.

Here is an example query, evaluated to example model 1:

```
?- query(1).
```

```
> Who loves Honey Bunny?
pumpkin
```

In model 1, only Pumpkin loves Honey Bunny. Our driver tries to find other instantiations for answers, but it—correctly—fails. So, all it displays is the answer `pumpkin`.

We could extend the driver, and let it ask again for a question, by adding a second clause for `query/1`. After all, the first clause will *always* fail (due to the usage of `fail` in it).

```
query(Example):-  
    query(Example).
```

Now we have changed our driver in a “never ending conversation”! Here is a snapshot of an example session:

```
?- query(1).  
  
> Who loves Honey Bunny?  
pumpkin  
  
> Who does not love Honey Bunny?  
mia  
vincent  
honey_bunny  
  
> Which robber loves Honey Bunny?  
pumpkin  
  
> Which robber does not love Honey Bunny?  
honey_bunny  
  
>
```

Recall the vocabulary and the content of example model 1, and note the way negated questions are answered. Handling negated questions in this correct way is due to our revised model checker of Chapter 1.

**Exercise 6.1.1** [intermediate] Extend the grammar fragment and the driver predicate in such a way that yes-no questions are covered as well.

**Exercise 6.1.2** [hard] Reimplement wh-questions by using the gap-threading technique to pass on the variable of the WH-phrase down the syntax tree, as required in ‘Who did Vincent kill?’ (For gap-threading, consult Pereira & Shieber.)

## 6.2 Natural Language Argumentation

We might want to let the computer decide whether a natural language argument is valid. (A natural language argument is a sequence of sentences, the last of which is called the *conclusion*, the rest, *premises*.) Here, for example, is a simple two premise natural language argument:

- (1) 
$$\frac{\begin{array}{l} \text{Vincent knows every boxer.} \\ \text{Butch is a boxer.} \end{array}}{\text{Vincent knows Butch.}}$$

This argument is *valid*. If the premises are true, then the conclusion is true too.

Now, we already have the basic tool needed to test arguments for validity, namely our first-order tableaux theorem prover. What we need to add is a driver which hands the theorem prover a list of formulas instead of just a single formula. The theorem prover will then attempt to make the premises true and the conclusion false. If it can't do this—that is, if it terminates with a closed tableau—then the argument is valid.

Let's implement a predicate which does this. We'll call it `validArgument/2`, and it will feed the theorem prover with a list of formulas, where the first formula of the list is the conclusion, and the rest of the list are premises. We will also need a predicate `premises/3` that turns a list of formulas in a list of signed, notated formulas.

```
validArgument([Conclusion|Premises],Qdepth):-
    notatedFormula(NotatedConclusion,[],f(Conclusion)),
    premises(Premises,[],NotatedPremises),
    saturate([[NotatedConclusion|NotatedPremises]],Qdepth).

premises([],N,N).
premises([P|Premises],SoFar,NotatedPremises):-
    notatedFormula(NotatedP,[],t(P)),
    premises(Premises,[NotatedP|SoFar],NotatedPremises).
```

The only thing missing is a driver that takes a natural language argument, gives the sentences in the argument to a DCG that builds first order representations, and then feeds the representations to `validArgument`. But this is easily done by a predicate called `argument/0`:

```
argument:-
    enterPremises(Premises),
    enterConclusion(Conclusion),
```

```
(
    validArgument([Conclusion|Premises],10),
    nl,write('This is a valid argument!'),nl,!
;
    nl,write('Not a valid argument...'),nl
).
```

When starting this predicate, the user is asked to enter some premises, and a conclusion, which are then passed through as argument of `validArgument/2` (we allow 10 applications of the universal rules). If a proof is found, this predicate prompts “This is a valid argument!”, otherwise it prints “Not a valid argument...”.

Entering the premises is done with the help of the following (recursive) predicate:

```
enterPremises(Premises):-
    nl, write('Enter premises (or Return to continue:)'),
    readLine(Input),
    (
        Input=[],!,
        Premises=[]
    ;
        d(SemPremise,Input,[]),
        betaConvert(SemPremise,ConvertedPremise),
        enterPremises(Others),
        Premises=[ConvertedPremise|Others]
    ).
```

This predicate—recursively—asks the user to enter premises and translates them into first-order logic, and returns a list of formulas. The recursion finishes if the user enters and empty sentence.

A similar predicate does this job for entering the conclusion:

```
enterConclusion(Conclusion):-
    nl, write('Enter conclusion:'),
    readLine(Input),
    d(SemConclusion,Input,[]),
    betaConvert(SemConclusion,Conclusion).
```

Time for a test session to see if this all works.

?- argument.

Enter premises (or Return to continue):

> Butch is a boxer.

Enter premises (or Return to continue):

> Vincent knows every boxer.

Enter premises (or Return to continue):

>

Enter conclusion:

> Vincent knows a boxer.

This is a valid argument!

Equally well, we can try and see if the whole thing works for arguments that are *not* valid. The following, for instance, is not a valid argument.

- (2)     If Mia snorts, then Vincent smokes.  
       Vincent smokes.  
       

---

       Mia snorts.

So let's try:

?- argument.

Enter premises (or Return to continue):

> If Mia snorts, then Vincent smokes.

Enter premises (or Return to continue):

> Vincent smokes.

Enter premises (or Return to continue):

>

Enter conclusion:

> Mia snorts.

Not a valid argument...

Now Prolog gives the appropriate response after entering the third sentence, as expected.

## Argumentation with Scope Ambiguities

Let's have a look at the following argument:

- (3) 
$$\frac{\begin{array}{l} \text{A woman loves every man.} \\ \text{Every boxer is a man.} \end{array}}{\text{A woman loves every boxer.}}$$

Is this a valid argument? The answer is: *sometime yes, sometimes no*. The premises are ambiguous, so it depends on which reading we give them. It *is* a valid argument if the first premise is understood as: there is a woman such that she loves every man. (That is, the reading where ‘a woman’ out-scopes ‘every man’.)

But, this is not the reading that `mainLambda.pl` gives us. And trying this example on our driver for natural language argumentation will generate an “invalid” as response. It would be nice to be able to test whether a natural language argument is valid under some reading of the premises. Obviously our program from Chapter 2 won't help us here, since it can't cope with scope ambiguities. However, if we consult `mainCooperStorage.pl` instead, we get both readings for the first premise:

```
?- s(Sem,[every,man,is,loved,by,a,woman],[[]]).

Sem = exists(Y,woman(Y)&forall(X,man(X)>love(Y,X))) ;

Sem = forall(X,man(X)>exists(Y,woman(Y)&love(Y,X))) ;

no
```

The first one is the reading we are interested in, the second isn't. So now we are able, in principle, to test arguments with scope ambiguities, and show, using our tools, that this argument has a valid reading.

**Exercise 6.2.1** Revise the `argument/1` driver in such a way that it handles scope ambiguities. Incorporate one of the programs from Chapter 3 (Cooper Storage, Keller Storage, or Hole Semantics).

## 6.3 Building Ontologies

Although we have discussed in detail how to build meaning representations for natural language expressions out of the representations of the words they consist of, so far we haven't

paid any attention to the meaning of the words themselves. For example, we simply assumed that the meaning of ‘boxer’ was adequately represented by the symbol BOXER. Even worse, we left ‘five dollar shake’ unanalyzed and represented it by FIVE\_DOLLAR\_SHAKE. In short, we have said nothing about *lexical semantics*.

Lexical semantics is a fascinating (and difficult) subject, and one we won’t be able to explore in detail in this book. Nonetheless, it is worth knowing that it is possible to say something useful about word meaning by thinking about the relationships that hold *between* words. To illustrate this, we will present a simple treatment of *nouns*. We will describe the fine structure of entities (that is, the things nouns denote) by designing an *ontology of concepts*. The work involved is essentially *classification*. That is, we are going to divide the concepts that make up the world into different classes. Some of these classes will be *disjoint*. (For example, we could decide that male and female entities are disjoint.) On the other hand, some classes will *inherit* properties of other classes. (For example, we could classify the noun ‘man’ as male. As male is disjoint from female, we could then infer that ‘man’ inherits the property of being disjoint from female.)

These two relations—disjointness and inheritance—are closely interconnected. Here is a tree structure of four nouns (‘organism’, ‘plant’, ‘animal’, and ‘human’) that shows why and how.

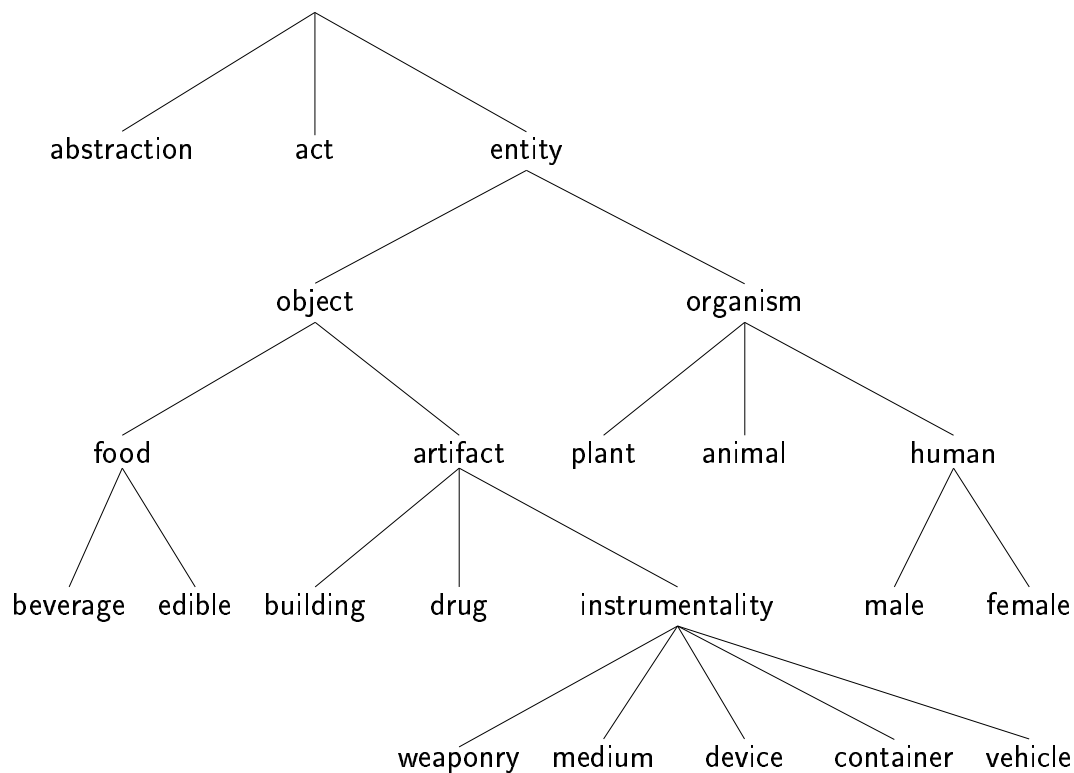

These are the kind of tree-structures that we will use to classify nouns, so it is important to know how to interpret them. First, all daughters of a mother node are disjoint. So, the tree above states that ‘plant’, ‘animal’, and ‘human’ are pairwise disjoint concepts. That is, according to this partial picture of the world, nothing can be a plant and an animal, nothing can be an animal and a human, and nothing can be a plant and a human. This classification (which is based on that used in the lexical database WordNet) seems to make sense. Of course one could quibble with the terminology—a biologist would insist that humans *are* animals—but for many purposes it is clearly a sensible classification.

The second kind of information this picture gives us concerns inheritance. All the daughter nodes inherit information from the mother nodes. According to the tree above, every ‘plant’ is an ‘organism’, every ‘animal’ is an ‘organism’, and every ‘human’ is an ‘organism’. Or to use the standard linguistic terminology for these relationships, ‘organism’ is a *hypernym* of ‘animal’, and ‘animal’ is a *hyponym* of ‘organism’. These relationships are *not* transitive. That is, while ‘object’ is a *hypernym* of ‘food’, and ‘food’ is a *hypernym* of ‘beverage’, the linguist would not say that ‘object’ was a *hypernym* of ‘beverage’. In graphical terms, to move to the hypernym we take one step up the tree to the mother node, and to move to a hyponym we move one step down to a daughter.

That's the basic idea. Let's apply it on a bigger scale, by classifying all the nouns in our lexicon. That is, we shall draw a tree ontology that covers all of the nouns in our lexicon. Now, obviously there are many ways to carry out this task, and it is also highly likely that if two different people classified the same set of nouns, they'd each come up with a different ontology, for everyone has a slightly different conception of the world. Is this a serious obstacle? For our purposes, no. We simply want to illustrate how important it is to provide *some* (consistent) picture of the world, and how to put this picture to work. But of course, if you want to adapt the tools provided in this book to some particular domain you will almost certainly want to extend the ontology provided below in various ways.

The classification of nouns that we will adopt is based on that provided by the lexical database WordNet. Here is the top structure of our ontology:

At the top of this structure we have ‘abstraction’ (a general concept formed by extracting common features from specific examples), ‘act’ (things that people do) and ‘entity’ (any concretely existing object). (You might want to argue that any ‘abstraction’ is a concretely existing entity. Fine: if you feel this way, change the tree so that ‘abstraction’ becomes a daughter of ‘entity’.) Then ‘entity’ is divided into ‘object’ (any non-living entity) and ‘organism’ (a living entity). The remaining classifications should be fairly self-explanatory.

This is the top structure of our ontology. And now, taking this tree as our point of departure, let's try to find our way through the world of nouns. That is, let's go through

our lexicon and relate each of the nouns to one of these nodes. Sometimes this is easy. For example, ‘episode’ and ‘joke’ are abstractions, ‘foot massage’ and ‘piercing’ are acts, a ‘five dollar shake’ is a beverage, and so on. Moreover, the framework outlined so far does enable us to deal with homonyms (words that have multiple unconnected meanings), as the reader is now asked to show.

**Exercise 6.3.1** [easy] Think of a way to put homonyms (words that have multiple unconnected meanings) in the ontology of nouns. For instance, according to WordNet, ‘boxer’ could be someone who fights with his fists for sport, a worker who packs things into containers, or a breed of stocky medium-sized short-haired dog with a brindled coat and square-jawed muzzle developed in Germany.

But what about nouns like ‘boss’, ‘boxer’, ‘owner’, or ‘criminal’? These should definitely be classified as human, but they can’t be classified as simply as male or female: they can be either. However if we extend the tree for ‘human’ using the ideas introduced so far, the only possibility is:

This is clearly *wrong*. It states that boxers are disjoint from bosses, and that owners are disjoint from male and female — in short, precisely what we need to avoid. What are we to do? A simple solution (and the one we shall adopt) is to add yet another kind of relation to the ontology tree: one that includes inheritance, but excludes disjointness. We will use dotted lines for this kind of relation. Applying this idea gives us the following tree:

Using this extension, it is reasonably straightforward to classify all the nouns in our little lexicon. And, as we shall see, this information will be useful in at least two ways: First, we will use it as background knowledge for general first-order inference tasks (we shall do so by translating the inheritance and disjointness relations into first-order formulas). Second, it will be the basic source for determining sortal conflicts, a simple form of inference we can encode directly in Prolog.

But before turning to inference, let’s turn to a more pressing question: how shall we represent the ontology? Actually, there’s an even better question: where shall we *store*

the ontology? And, since we want to state the relations between *words*, what could be a better place to choose than the the lexicon (after all, this was specifically designed to contain information about words)? So let's agree to code the ontology tree in our lexicon. Here's how we shall do this:

```
lexicon(noun,car,[car],[vehicle]).
lexicon(noun,chainsaw,[chainsaw],[device]).
lexicon(noun,criminal,[criminal],human).
lexicon(noun,customer,[customer],human).
lexicon(noun,drug,[drug],[artifact]).
lexicon(noun,entity,[entity],[top]).
lexicon(noun,episode,[episode],abstraction).
lexicon(noun,female,[female],[human]).
```

For each noun in the lexicon, we fill the last slot with its hypernym noun. With the exception of `top`, all the hypernyms are part of the lexicon, too. Words that encode their hypernyms in square brackets (such as `car` and `chainsaw` above) are disjoint with respect to other words with the same hypernym (that is, square brackets encode the solid lines in the tree). On the other hand, words that don't do this (such as `criminal` and `customer`) are not required to be disjoint from other words with the same hypernym (that is, hypernyms listed without square brackets indicate that the dotted line relationship introduced in the previous tree diagram holds).

An important remark. As we've already remarked, the hypernym relation is not transitive. These relations are *not* transitive. That is, while 'object' is a *hyponym* of 'food', and 'food' is a *hyponym* of 'beverage', 'object' is not a *hyponym* of 'beverage'. Nonetheless, it is certainly true that anything that is a beverage is an object, and when performing inference we will be interested in drawing such conclusions, and this means that we will need to chain our way through the hypernym relation. But this leads to a practical point: if we have been careless, and specified the hypernym relation wrongly, we may get silly answers when we carry out such chaining. In particular we need to take care that there are no words  $w, v_1, v_2, \dots, v_n$  in our lexicon such that  $w$  is a hypernym of  $v_1$ ,  $v_1$  is a hypernym of  $v_2$ ,  $\dots$ , and  $v_n$  is a hypernym of  $w$ . It would be useful to have a Prolog utility that checks that our ontological specifications don't contain cycles, and the next exercise asks the reader to provide one.

**Exercise 6.3.2** Write a checker that browses through the lexicon, checking that it is never possible to cycle back to a word by moving along the hypernym relation for nouns.

Once we've stored our ontology in the lexicon, we want to use the information it contains to perform inference. Actually, we're going to do so in two distinct ways: by compiling the ontology into first-order formulas (so that we can use general first-order inference methods) and by using more restricted (but more efficient) Prolog-based inference.

Let's first see how to compile ontologies into first-order formulas. If P is a mother of Q, then we can infer that for all things that are Q, they also are P. And if Q and R have the same mother P, and both relationships are shown with a *solid* line, then we infer that no thing that is Q, is R. So, from the following tree

we can derive the formulas:  $\forall x(Q(x) \rightarrow P(x))$ ,  $\forall x(R(x) \rightarrow P(x))$ ,  $\forall x(S(x) \rightarrow P(x))$ ,  $\forall x(T(x) \rightarrow P(x))$ , and also  $\forall x(Q(x) \rightarrow \neg R(x))$ .

**Exercise 6.3.3** Do we need, in addition to the formulas above, also the formula  $\forall x(R(x) \rightarrow \neg Q(x))$ ? Why or why not?

In Prolog, this translation is implemented as follows:

```

generateOntology(Formulas):-
    generateIsa(I0),
    generateDisjoint(I0-I1,I2),
    isa2fol(I1,[],-F),
    isa2fol(I2,F-Formulas).
  
```

With the help of the Prolog built-in `setof` predicate, we collect all the inheritance relations in terms of the form `isa(Hypo,Hyper)`.

```

generateIsa(I):-
    setof(isa(Hypo,Hyper),Words^lexicon(noun,Hypo,Words,Hyper),I).
  
```

On the basis of this list, we calculate a list of `disjoint(A,B)` terms, and update the list of `isa/2` relations, by removing the square brackets from the hypernym (we don't need these anymore).

```

generateDisjoint([],[]).

generateDisjoint([isa(A,[Hyper])|L1]-[isa(A,Hyper)|L2],I3):-!,
    findall(disjoint(A,B),member(isa(B,[Hyper]),L1),I1),
    generateDisjoint(L1-L2,I2),
    append(I1,I2,I3).

generateDisjoint([isa(A,Hyper)|L1]-[isa(A,Hyper)|L2],I):-
    generateDisjoint(L1-L2,I).
  
```

These lists contain the inheritance information (`isa/2`) and the disjointness relations (by `disjoint/2`). Now the translation into first-order representations is straightforward:

```
isa2fol([],A-A):- !.

isa2fol([isa(S1,[S2])|L],A1-[forall(X,F1 > F2)|A2]):- !,
    compose(F1,S1,[X]),
    compose(F2,S2,[X]),
    isa2fol(L,A1-A2).

isa2fol([isa(S1,S2)|L],A1-[forall(X,F1 > F2)|A2]):-
    compose(F1,S1,[X]),
    compose(F2,S2,[X]),
    isa2fol(L,A1-A2).

isa2fol([disjoint(S1,S2)|L],A1-[forall(X,F1 > ~ F2)|A2]):-
    compose(F1,S1,[X]),
    compose(F2,S2,[X]),
    isa2fol(L,A1-A2).
```

Running this predicate gives us a list of terms that look like:

```
?- generateOntology(0).

0 = [forall(A,abstraction(A)>top(A)),
     forall(B,act(B)>top(B)),
     forall(C,animal(C)>organism(C)),
     forall(D,artifact(D)>object(D)),
     forall(E,beverage(E)>food(E)),
     forall(F,bkburger(F)>edible(F)),
     forall(G,boss(G)>human(G)),.....]
```

This compilation opens the door to using general first-order inference techniques.

But sometimes we will want to use the ontology to perform inference directly in Prolog; while less general, this can be far more efficient. For instance, we would like to test whether something can be both a ‘radio’ and a ‘gun’, or both an ‘artifact’ and ‘suitcase’. We do this by the predicate `consistent/2`.

```
consistent(X,Y):-
    generateIsa(I),
    generateDisjoint(I-Isa,Disjoint),
    \+ inconsistent(X,Y,Isa,Disjoint).
```

We shall say that two items from our ontology are consistent if we can't prove that they are inconsistent. So when are two items inconsistent? First of all, if they are disjoint:

```
inconsistent(X,Y,_,Disjoint):-  
    member(disjoint(X,Y),Disjoint).  
  
inconsistent(X,Y,_,Disjoint):-  
    member(disjoint(Y,X),Disjoint).
```

Second, they are inconsistent if by chaining up the tree from the first item, we can find a a hypernym that is inconsistent with the other item.

```
inconsistent(X,Y,Isa,Disjoint):-  
    member(isa(X,Z),Isa),  
    inconsistent(Z,Y,Isa,Disjoint).  
  
inconsistent(X,Y,Isa,Disjoint):-  
    member(isa(Y,Z),Isa),  
    inconsistent(X,Z,Isa,Disjoint).
```

Now we can test this predicate with queries such as:

```
?- consistent(female,boss).  
  
yes  
  
?- consistent(male,radio).  
  
no
```

**Exercise 6.3.4** Our Prolog implementation of the `consistent/2` predicate is rather inefficient. Every time this predicate is put to work, it traverses through the entire lexicon to build up the set of `isa/2` and `disjoint/2` terms. But as the lexicon is quite likely to be static during parsing or semantic analysis, the same work is done for every call on `consistent/2`. Change this, by declaring `isa/2` and `disjoint/2` as dynamic predicates, that are asserted to Prolog's database at initialization of the module.

**Exercise 6.3.5** [project] Use the ontology for nouns above and add sortal constraints to the semantics of verbs, such that 'Mia drinks a restaurant' is rejected, but 'Mia drinks a five dollar shake' is accepted.

## 6.4 Logical Redundancies

There are many important issues to do with quantifier scoping which we have ignored. One such issue has to do with logical redundancies: our algorithm will generate two logically equivalent readings for ‘Every boxer loves every woman’, or for ‘A man saw a woman’.

**Exercise 6.4.1** [project] Write an algorithm that, after generating all the scoped representations with storage or hole semantics, checks whether these are logically equivalent. Use either our first-order tableaux program, or an “off-the-shelf” theorem prover to carry out the reasoning tasks.

Further, as we mentioned in Chapter 3, simply generating all possible permutations of quantifier scope is naive—ideally, we want world knowledge to filter out some of the possibilities. But if can think of a portion of world knowledge coded as first-order formulas, that are relevant to this problem, then we can use automated reasoning to perform the required filtration. For example, given a sentence with the noun phrase ‘a fist of every boxer’, our ‘generate all possibility’ methods will happily generate readings in which a fist is shared by several boxers, which is biologically implausible. Another example is the sentence ‘Every car has a radio’, in which the reading where all the cars in the domain share the same radio is quite unlikely.

**Exercise 6.4.2** [project] Design a first-order theory (a set of formulas that put further constraints on the objects in our domain), that eliminate unwanted readings that are produced by scoping algorithms. Use either our first-order tableaux program, or an “off-the-shelf” theorem prover to carry out the reasoning tasks.

### Software Summary of Chapter 6

`nlQuestions.pl` Simple example that shows how to combine model checking and semantic construction to get a system for natural language queries. (page 249)

`nlArgumentation.pl` Combines the theorem prover with a natural language interface to handle natural language argumentation. (page 251)

`semOntology` Predicates for working with the semantic ontology (page 253)

## Notes

### Wordnets

WordNet is a lexical database for English nouns, verbs, adjectives, and adverbs (Miller 1995). What WordNet makes a winner is that it has a huge coverage, and that all its sources are electronically available, in different kinds of frameworks (including Prolog). Probably the best introduction to WordNet is the recently published book (Fellbaum 1998). If you can't get hold of this book, read for an introduction the "Five papers on WordNet" (available on the Web), which explains the basic philosophy behind WordNet, and the structure and organization of its components.

### Eliminating logically equivalent readings

Removing non-redundant scopings is not only interesting, it also reduces processing time. Nevertheless, relatively little work is done on eliminating logically equivalent readings. Vestre describes an algorithm that generates non-redundant quantifier scopings (Vestre 1991), without appealing to any kind of automated reasoning. A more general strategy is approached by Gabsdil and Striegnitz (1999), who use off-the-shelf inference engines to eliminate equivalent readings generated by a standard scoping algorithm, such as those provided in Chapter 3.

# Appendix A

## Propositional Languages

The quantifier-free fragment of any first-order language (as the terminology suggests) simply consists of all formulas of the language that contain no occurrences of the symbols  $\exists$  or  $\forall$ . For example,  $\text{ROBBER}(\text{PUMPKIN})$ ,  $\text{CUSTOMER}(\text{MIA})$ ,  $\text{CUSTOMER}(y)$ , and

$$\text{CUSTOMER}(y) \rightarrow \text{LOVE}(\text{VINCENT}, y)$$

are all quantifier-free formulas. On the other hand,

$$\forall y[\text{CUSTOMER}(y) \rightarrow \text{LOVE}(\text{VINCENT}, y)]$$

isn't, as it contains an occurrence of the quantifier  $\forall$ .

The key thing to note about quantifier-free formulas is the following. Suppose we are given a model  $\mathbf{M}$  (of appropriate vocabulary) and an assignment  $g$  in  $\mathbf{M}$ . Now, normally we need to work with two semantic notions: satisfaction for arbitrary formulas and truth for sentences. However, when working with quantifier-free formulas, there are no bound variables to complicate matters, so this distinction is unnecessary. In fact, when working with a quantifier-free fragment, we may as well view each variable  $x$  as a constant interpreted by  $g(x)$ . If we do this, then every quantifier-free formula is either true or false in  $\mathbf{M}$  with respect to  $g$ . Moreover, it is obvious how to calculate the semantic value of complex sentences: conjunctions will be true if and only if both conjuncts are true, disjunctions will be true if and only if at least one disjunct is true, a negated formula will be true if and only if the formula itself is not true, and so on. (In short, we basically need to make the truth table calculations, which the reader is probably familiar with.)

This means we can simplify our notation somewhat. Because we don't have quantifiers, the internal structure of atomic formulas is irrelevant, for we're never going to bind any free variables they may contain. All that is important is whether the atomic symbols are true

or false, and how they are joined together using Boolean operators. For example, while it may be mnemonically helpful to choose propositional symbols such as CUSTOMER( $x$ ) or LOVE(VINCENT,MIA), we lose nothing if we replace them by simpler symbols such as  $p$  and  $q$ . Following this line of thought leads us to define *propositional languages*. To specify a propositional language, we first say which symbols we are going to start with. (A fairly standard choice is  $p, q, r, s, t$ , and so on, often decorated with superscripts and subscripts: for example,  $p'', r''',$  or  $q_2$ .) The chosen symbols are called proposition symbols, or atomic sentences. Complex sentences are built up using the standard Boolean connectives (for example,  $\neg, \wedge, \vee$  and  $\rightarrow$ ) in the obvious way, and the truth values of complex sentences are calculated using the familiar truth table rules.

In short, propositional languages are essentially a simple notation for representing the quantifier-free formulas of first-order languages. When we devise inference mechanisms for first order logic in Chapters 4 and 5, it turns out to be sensible to first investigate inference methods for the quantifier free fragment (we do this in Chapter 4), and only then turn to the problem for the full first order language (the task of Chapter 5). Thus in Chapter 4, we make use of the simpler propositional notation just defined.

# Appendix B

## Type Theory

### But What Does It All Mean?

We have given an informal, computationally oriented, introduction to the lambda calculus and its applications in semantic construction. We adopted a rather procedural perspective, encouraging the reader to think of the lambda calculus as a programming language—indeed, as the sort of language that emerges when one tries to generalize straightforward logic programming approaches to semantic construction (such as that of experiment 2).

However our account hasn't discussed one interesting issue: what do lambda expressions actually mean? Hopefully the reader now has a pretty firm grasp of what one can *do* with lambda expressions—but is one forced to think of lambda expressions purely procedurally? As we are associating lambda expressions with expressions of natural language, it would be nice if we could give them some kind of model theoretic interpretation.

Actually, there's something even more basic we haven't done: we haven't been precise about what counts as a  $\lambda$ -expression! Moreover—as the industrious reader may already have observed—if one takes an 'anything goes' attitude, it is possible to form some pretty wild (and indeed, wildly pretty) expressions. For example, consider the following expression:

$$\lambda x.(x@x)@x$$

Is this a legitimate lambda expression? Suppose we functionally apply this expression to itself (after all, nothing we have said rules out self-application). That is:

$$(\lambda x.(x@x)@x)@(\lambda x.(x@x)@x)$$

If we now apply  $\beta$ -conversion we get:

$$((\lambda x.(x@x)@x)@(\lambda x.(x@x)@x))@(\lambda x.(x@x)@x)$$

But note this is just the functional application followed by an additional occurrence of  $\lambda x.(x@x)@x$ ! Obviously we can go on applying  $\beta$ -conversion as often as we like, producing ever longer expressions as we do so. Now, this is very interesting—but is it the sort of thing we had in mind when we decided to use the lambda calculus?

In this appendix, we shall briefly discuss some of these issues. The main points we wish to make are that there are different versions of the lambda calculus, useful for different purposes, and that both major variants of the lambda calculus can be given model theoretic interpretations in terms of functions and arguments. The reader interested in learning more is encouraged to follow up the references given in the Notes of Chapter 2.

The lambda calculus comes in two main varieties: the *untyped* lambda calculus, and the *typed* lambda calculus. Both can be regarded as programming languages, but they are very different.

The untyped lambda calculus adopts an ‘anything goes’ attitude to functional application. For example,  $\lambda x.(x@x)@x$  is a perfectly reasonable expression in untyped lambda calculus, and it is fine to apply it to itself as we did above. The untyped lambda calculus is relevant to the study of natural language (explaining various natural language phenomena seems to demand some form of self-application). Moreover, it is relevant to functional programming (the core of the programming language LISP is essentially the untyped lambda calculus). Finally, it does have a model-theoretic semantics, indeed a very beautiful one. As one might suspect, this semantics interprets abstractions as certain kinds of functions. The primary difficulty is to find suitable collections of functions in which the idea of self application can be captured. (In standard set theory, functions can’t apply to themselves, so constructing function spaces with the structure necessary to model self application is a non-trivial exercise.) There are a variety of solutions to this problem, some of which are very elegant indeed.

There are many kinds of typed lambda calculi. The one we shall discuss is called the *simply typed lambda calculus*.

Natural language semanticists generally make use of some version of the simply typed lambda calculus. The key feature of the simply typed lambda calculus is that it adopts a very restrictive approach to functional application. “If it doesn’t fit, don’t force it”, and typed systems have exacting notions about what fits. Let’s discuss the idea of simple typing in a little more detail.

To build the kinds of representations we have been making use of in simply typed lambda calculus, we would proceed as follows. First we would specify the set of types. There would be infinitely many of these, namely (1) the type  $e$  of individuals, (2) the type  $t$  of truth values, and (3) for any types  $\tau_1$  and  $\tau_2$ , the function type  $\langle \tau_1, \tau_2 \rangle$ . Second, we would specify our logical language. This would contain all the familiar first order symbols, but in addition it would contain an infinite collection of variables of each type (the ordinary first

order variables, which range over individuals, would now be thought of as the set of type  $e$  variables) together with the  $\lambda$  operator.

In the typed lambda calculus, every expression receives a *unique* type. The key clauses that ensures this are the definitions of abstraction and functional application. First, if  $\mathcal{E}$  is a lambda expression of type  $\tau_2$ , and  $v$  a variable of type  $\tau_1$  then  $\lambda v.\mathcal{E}$  is a lambda expression of type  $\langle\tau_1, \tau_2\rangle$ . In short, it matters which type of variable we abstract over. Abstracting with respect to different types of variables results in abstractions with different types. Second, if  $\mathcal{E}$  is a lambda expression of type  $\langle\tau_1, \tau_2\rangle$ , and  $\mathcal{E}'$  is a lambda expression of type  $\tau_1$  then we are permitted to functionally apply  $\mathcal{E}$  to  $\mathcal{E}'$ . If we do this, the application has type  $\tau_2$ . In short, we are only allowed to perform functional application when the types  $\mathcal{E}$  and  $\mathcal{E}'$  fit together correctly, *and only then*. The intuition is that the types tell us what the domain and range of each expression is, and if these don't match, application is not permitted. Note, moreover, that the type of the application is determined by the types of  $\mathcal{E}$  and  $\mathcal{E}'$ . In effect, we have imposed a very strict type discipline on our formalism. The typed lambda calculus is a programming language, but when we use it we have to abide by very strict guidelines.

This has a number of consequences. For a start, self-application is impossible. (To use  $\mathcal{E}$  as a functor, it must have a function type, say  $\langle\tau_1, \tau_2\rangle$ . But then its arguments must have type  $\tau_1$ . So  $\mathcal{E}$  can't be one of its own arguments.) Moreover, it is very straightforward to give a semantics to such systems. Given any model  $M$ , the denotation  $D_e$  of type  $e$  expressions are the elements of the model, the permitted denotations  $D_t$  of the type  $t$  expressions are TRUE and FALSE, and the permitted denotations  $D_{\langle\tau_1, \tau_2\rangle}$  of type  $\langle\tau_1, \tau_2\rangle$  expressions are functions whose domain is  $D_{\tau_1}$  and whose range is  $D_{\tau_2}$ . In short, expressions of the simply typed lambda calculus are interpreted using a straightforward, inductively defined, function hierarchy.

Which particular functions are actually used? Consider  $\lambda x.MAN(x)$ , where  $x$  is an ordinary first order variable. Now,  $MAN(x)$  is a formula, something that can be TRUE or FALSE, so this has type  $t$ . As was already mentioned, first-order variables are viewed as type  $e$  variables, hence it follows that the abstraction  $\lambda x.MAN(x)$  has type  $\langle e, t\rangle$ . That is, it must be interpreted by a function from the set of individuals to the set of truth values. But which one? In fact, it would be interpreted by the function which, when given an individual from the domain of quantification as argument, returns TRUE if that individual is a man, and FALSE otherwise. To put it another way, it is interpreted using the function which exactly characterizes the subset of the model consisting of all men. But this subset is precisely the subset that the standard first-order semantics uses to interpret  $MAN$ . In short, the 'functional interpretation' of lambda expressions is set up so that, via the mechanism of such *characteristic functions*, it meshes perfectly with the ordinary first order interpretation.

By building over this base in a fairly straightforward way, the interpretation can be extended to cover all lambda expressions. For example, the expression

$$\lambda P.\exists x(WOMAN(x)\wedge P@x)$$

would be interpreted as a function which when given the type of function that  $P$  denotes as argument (and  $P$  denotes type  $\langle e, t \rangle$  functions, like the characteristic function of MAN) returns a type  $t$  value (that is, either TRUE or FALSE). Admittedly, thinking in terms of functions that take other functions as arguments and return functions as values can get pretty tedious, but the basic idea is straightforward, and for applications in natural language semantics, only a very small part of the function hierarchy tends to be used.

In short, throughout this book we have been talking about the lambda calculus as a mechanism for marking ‘missing information’, and we have exploited the mechanisms of functional application and  $\beta$ -conversion as a way of moving such missing information to where we want it. But in fact there is nothing at all mysterious about this ‘missing information’ metaphor. It is possible to give precise mathematical models of missing information in terms of functions and arguments. An abstraction is interpreted as a function, and the ‘missing information’ is simply the argument we will later supply it with. Indeed, a variety of models are possible, depending on whether one wants to work with typed or untyped versions of the lambda calculus.

**Exercise B.0.1** Does our implementation of  $\beta$ -conversion allow self-application?

**Exercise B.0.2** What happens when you functionally apply the formula  $\lambda x.x @ x$  to itself?

# Appendix C

## Theorem Provers and Model Builders

Automated reasoning has seen an enormous increase of performance of (especially first-order) inference engines and model builders. This appendix is a guide to a number of useful reasoning engines for computational semantics.

### Theorem Provers

- **BLIKSEM**  
Resolution based theorem prover for first order logic with equality (Hans de Nivelle). Almost as fast as the speed of light.  
URL: <http://turing.wins.uva.nl/~mdr/ACLG/Provers/Bliksem/bliksem.html>
- **SPASS**  
First-order theorem prover (Christoph Weidenbach et al.)  
Winner at the CASC-15 in the divisions FOF and SAT.  
URL: <http://spass.mpi-sb.mpg.de/>.
- **FDPLL:**  
Or, if you prefer, the “First-Order Davis-Putnam-Loveland-Logeman” theorem prover (Peter Baumgartner). Good at satisfiable problems.  
URL: <http://www.uni-koblenz.de/~peter/FDPLL/>
- **OTTER**  
The ‘classical’ theorem prover by W. McCune.  
URL: <http://www-unix.mcs.anl.gov/AR/otter/>

## Model Builders

- **MACE**  
Short for “Model and Counter-Examples”. Mace is a Model builder for first-order logic with equality (McCune). Got the first price at CASC-16 in division SAT (working in tandem with OTTER).  
URL: <http://www-unix.mcs.anl.gov/AR/mace/>
- **SATCHMO**  
Satchmo is a model generator for first-order theories, implemented in Prolog.  
URL: <http://www.pms.informatik.uni-muenchen.de/software/>
- **KIMBA**  
Kimba is an Higher-Order Model Generator, a deduction system for abductive or circumscriptive reasoning within linguistic applications (Karsten Konrad).  
URL: <http://www.ags.uni-sb.de/~konrad/kimba.html>

## Systems

- **MATHWEB**  
This system for automated theorem proving connects a wide-range of mathematical services by a common, mathematical software bus (Franke and Kohlhasse 1999).  
URL: <http://www.ags.uni-sb.de/~omega/www/mathweb.html>

# Appendix D

## Prolog in a Nutshell

### What is Prolog?

Prolog is one of the most important programming languages in Computational Linguistics and Artificial Intelligence. Two key features distinguish Prolog from other programming languages: its *declarative* nature, and its extensive use of *unification*. Ideally, in Prolog we simply state the nature of the problem, and let the Prolog unification-driven inference engine search for a solution.

### The Basics

There are actually only three basic constructs in Prolog: *facts*, *rules*, and *queries*. A set of facts and rules — that is, a *knowledge base* — is all a Prolog program consists of. Facts are used to state things that are unconditionally true of the domain of interest. For example, we can state that Mia and Jody are women by putting the facts

```
woman(mia).  
woman(jody).
```

in our knowledge base. Rules relate facts by logical implications. We can add to our knowledge base the conditional information that Mia plays air-guitar *if* she listens to music as follows:

```
playsAirGuitar(mia):-  
    listensToMusic(mia).
```

The `:-` should be read as “if”, or “is implied by”. The part on the left hand side of the `:-` is called the *head* of the rule, the part on the right hand side the *body*. (Incidentally, note that we can view a fact as a rule with an empty body. That is, we can think of facts as ‘conditionals that don’t have any antecedent conditions’.) The facts and rules contained in a knowledge base are called *clauses*. The collection of all clauses in a knowledge base that have the same head is called a *predicate*.

Posing queries makes the Prolog inference engine try to deduce a positive answer from the information contained in the knowledge base. There are two basic circumstances under which Prolog can return a positive answer. The first, and simplest, is when the question posed is one of the facts listed in the knowledge base. The second is when Prolog can deduce the positive answer by using the deduction rule called *modus ponens*. That is, if `head :- body` and `body` are both in the knowledge base, then Prolog can deduce that `head` is true.

Let’s consider an example. We can ask Prolog whether Mia is a woman by posing the query

```
?- woman(mia).
```

and Prolog will answer “yes”, since this is a fact in the knowledge base. However, if we ask whether Mia plays air-guitar by posing the query

```
?- playsAirGuitar(mia).
```

its answer is “no”. First, this fact is not recorded in the knowledge base. Second, it cannot infer that Mia plays air-guitar as there is nothing in the knowledge base stating that Mia is listening to music (thus Prolog assumes that this is false) and hence we cannot make use of the only rule we have in our knowledge base. On the other hand, if the knowledge base had contained the additional fact

```
listensToMusic(mia).
```

then Prolog would have responded “yes”, since it could then have deduced by *modus ponens* that Mia plays air-guitar.

Jumping ahead slightly, there are two things that make Prolog so powerful. The first is that it is capable of ‘chaining together’ uses of *modus ponens*. The second is that Prolog has a powerful mechanism (described later) called *unification*, which lets it handle variables. This combination of chained *modus ponens* and sophisticated variable handling enables it to draw far more interesting inferences than our rather trivial examples might suggest.

The comma `,` expresses logical conjunction in Prolog. We can change the rule above by adding another condition to its body:

```
playsAirGuitar(mia):-  
    listensToMusic(mia),  
    happy(mia).
```

Now the rule reads: Mia plays air-guitar if she listens to music, *and* if she is happy. We can also express disjunction in Prolog. Let's change the rule to:

```
playsAirGuitar(mia):-  
    listensToMusic(mia);  
    happy(mia).
```

The `;` should be read as *or*, so here we have a rule stating that Mia plays air-guitar if she listens to music, *or* if she is happy.

However there is another (much more commonly used) way of expressing disjunctive conditions: we simply list a number of clauses that have the same head. For example, the following two rules mean exactly the same as the previous rule:

```
playsAirGuitar(mia):-  
    listensToMusic(mia).  
playsAirGuitar(mia):-  
    happy(mia).
```

In fact, disjunctions are almost always expressed using such multiple rules; extensive use of semicolon makes Prolog code pretty hard to read.

## Syntax

What exactly are the syntactic entities such as `woman(jody)` and `playsAirGuitar(mia)` that we use to build facts, rules, and queries? They are called *terms*, and there are three kinds of terms in Prolog: atoms, variables, and complex terms. An atom is a sequence of characters starting with a lowercase character. A variable is also a sequence of characters, but it must start with an uppercase character or an underscore. So `mia` and `airGuitar` are atoms, while `X`, `Mayonnaise`, and `_mayonnaise` are variables.

Complex terms are build out of a *functor* and a sequence of *arguments*. The arguments are put in ordinary brackets, separated by commas, and placed after the functor. The functor *must* be an atom. That is, variables *cannot* be used as functors. On the other hand, arguments can be any kind of term. For example

```
hide(X,father(butch))
```

is a complex term. Its functor is `hide`, and it has two arguments: the variable `X`, and the complex term `father(butch)`.

The number of arguments that a complex term has is called its *arity*. For instance, `woman(mia)` is a complex term with arity 1, while `loves(vincent,mia)` is a complex term with arity 2.

Arity is important to Prolog. Prolog would be quite happy for us to use two predicates with the same functor but with a different number of arguments (for example, `love(vincent,mia)`, and `love(vincent,marcellus,mia)`) in the same program. However, if we insisted on doing this, Prolog would treat the two place `love` and the three place `love` as completely different predicates.

When we need to talk about predicates and how we intend to use them (for example, in documentation) it is usual to use a suffix `/` followed by a number to indicate the predicate's arity. For example, if we were talking about the `playsAirGuitar` predicate we would write it as `playsAirGuitar/1` to indicate that it takes one argument. We make use of this convention in the book.

## Unification

Variables allow us to make general statements in Prolog. For example, to declare that every woman likes a foot massage, we add the following rules to the database:

```
likeFootMessage(X):-  
    woman(X).
```

It can be read as: `X` likes a foot massage, if `X` is a woman. The nice thing about variables is that they have no fixed values. They can be instantiated with a value by the process of unification. If we pose the query

```
?- likeFootMessage(mia).
```

the variable `X` is *unified* with the atom `mia`, and Prolog tries to prove that `woman(mia)` can be inferred from the knowledge base. Two terms are unifiable if they are the same atoms, or if one of them is a variable, or if they are both complex terms with the same functor name and arity, and all corresponding arguments unify. Unification makes terms identical. It is the heart of the engine that drives Prolog.

Prolog has a built-in operator for unification: the `=`. By querying the goal

```
?- X = butch.
```

the variable `X` gets unified with the atom `butch` and the goal succeeds.

## Recursion

Predicates can be defined recursively. Roughly speaking, a predicate is recursively defined if one or more rules in its definition refers to itself. Here's an example:

```
moreExpensive(X,Y):-
    costsaLittleMore(X,Y).

moreExpensive(X,Y):-
    costsaLittleMore(X,Z),
    moreExpensive(Z,Y).
```

The definition of the `moreExpensive/2` predicate is fairly typical of the way recursive predicates are defined in Prolog. Clearly, `moreExpensive/2` is (at least partially) defined in terms of itself, as the more `moreExpensive` functor occurs on both the left and right hand sides of the second rule. Note, however, that there is an 'escape' from this circularity. This is provided by the `costsaLittleMore` predicate, which occurs in both the first and second rules. (Significantly, the right hand side of the first rule makes no mention of `moreExpensive`.)

Let's see how Prolog makes use of such definitions. Suppose we had the following facts in our knowledge base:

```
costsaLittleMore(royaleWithCheese,bigKahunaBurger).

costsaLittleMore(fiveDollarShake,royaleWithCheese).
```

If we pose the query

```
?- moreExpensive(fiveDollarShake,bigKahunaBurger).
```

then Prolog goes to work as follows. First, it tries to make use of the first rule listed concerning `moreExpensive`. This tells it that  $X$  is more expensive than  $Y$  if  $X$  costs a little more than  $Y$ , but as the knowledge base doesn't contain the information that a five dollar shake costs a little more than a big kahuna burger, this is no help. So, Prolog tries to make use of the second rule. By unifying  $X$  with `fiveDollarShake` and  $Y$  with `bigKahunaBurger` it obtains the following goal:

```
?- costsaLittleMore(fiveDollarShake,Z),
    moreExpensive(Z,bigKahunaBurger).
```

Prolog deduces `moreExpensive(fiveDollarShake,bigKahunaBurger)` if it can find a value for  $Z$  such that, firstly,

```
?- costsaLittleMore(fiveDollarShake,Z).
```

is deducible, and secondly,

```
?- moreExpensive(Z,bigKahunaBurger).
```

is deducible too. But there is such a value for Z: `royaleWithCheese`. It is immediate that

```
?- costsaLittleMore(fiveDollarShake,royaleWithCheese).
```

will succeed, for this fact is listed in the knowledge base. Deducing

```
?- moreExpensive(royaleWithCheese,bigKahunaBurger).
```

is almost as simple, for the first clause of `moreExpensive/2` reduces this goal to deducing

```
?- costsaLittleMore(royaleWithCheese,bigKahunBurger).
```

and this is a fact listed in the knowledge base.

There is one very important thing you should bear in mind when working with recursion: a recursive predicate should always have at least two clauses: a non-recursive one (the clause that stops the recursion at some point, otherwise Prolog would never be able to finish a proof!), and one that contains the recursion. In our example, the first clause of `more_expensive/2` is the non-recursive clause, and the second clause contains the recursion. (Note that the order of these two clauses in the knowledge base is not important!)

## Lists

Lists are recursive data structures in Prolog. The recursive definition of a list runs as follows. First, the empty list is a list. Second, a complex term is a list if it consists of two items, the first of which is a term (often referred to as *first*), and the second of which is a list (often referred to as *rest* or *the rest list*).

Square brackets indicate lists. The empty list is written as `[]`. The list operator `|` separates the first item of a list from the rest list. For example, here is a list with three items:

```
[butch|[pumpkin|[marsellus|[]]]]
```

When working with lists, Prolog always makes use of such recursive first/rest representations, and for some purposes it is important to know this. Mercifully, however, Prolog also offers a more readable form of list representation. The same list can be declared as:

```
[butch,pumpkin,marsellus]
```

Prolog will quite happily accept lists in this more palatable notation as input, and moreover, it does its best to use this notation for its output.

Note that the items in a list need not only be atoms: they can be any Prolog term, including lists. For example

```
[vincent,[honey_bunny,pumpkin],[marsellus,mia]]
```

is a perfectly good list.

Since lists are recursive data structures, most of the predicates that work on lists, are defined using recursive predicates. The simplest example is the `member/2` predicate, which is given in the program library.

## Operators

Many newcomers to Prolog find the word *operator* rather misleading, for Prolog's operator's don't actually operate on anything, or indeed do anything at all. They are simply a notational device that Prolog offers to represent complex terms in a more readable fashion.

For example, suppose that we want to use `not` as the functor expressing sentence negation, and `and` as the functor expressing sentence conjunction. Then the term representing Butch boxes and Vincent doesn't dance would be:

```
and(butch_boxes,not(vincent_dances)).
```

It would be nicer if we could use the more familiar notation in which the conjunction symbol stands between the two sentences it conjoins. That is, we would prefer the following representation:

```
butch_boxes and not vincent_dances
```

The following *operator definitions* let us do precisely this.

```
:- op(30,yfx,and).  
:- op(20,fy,not).
```

The `and` is declared as an infix operator by `yfx` with precedence value of 30. The `y` represents an argument (in this case the left argument of `&`) whose precedence is lower or equal of the operator. The `x` represents an argument (the right argument of `and`) whose precedence value must be strictly lower than that of the operator (30, in this case). The `not` is defined as a prefix operator with precedence 20, and an argument that should have a precedence value lower or equal to 20.

More generally, Prolog allows us to define our own infix, prefix and postfix operators. Operator names must be atoms. When we declare a new operator, we also have to state its precedence and those of its arguments (in order for Prolog to disambiguate expressions with more than one operator).

A very important final remark about operators: Prolog is featured with a set of special predefined operators, that *have* a meaning. Among these is the `=` for unification as we saw before and `\+` for negation as we will see later. Other predefined operators we use in the programs of this book are the infix operators `==` and `\==`. The goal `X == Y` succeeds if `X` and `Y` are identical terms (That is, they should have the same structure, even variables should have the same name — unification plays no role here!). On the other hand, `\==` checks whether its arguments are *not* identical.

## Arithmetic

Prolog contains some built-in operators for handling integer arithmetic. These include `*`, `/`, `+`, `-` (for multiplication, division, addition, and subtraction, respectively) and `>`, `<` for comparing numbers.

These symbols, however, are just ordinary Prolog operators. That is, they are just a user friendly notation for writing arithmetic expressions: they *don't* carry out the actual arithmetic. For example, posing the query

```
?- X = 1 + 1.
```

unifies the variable `X` with the complex term `1 + 1`, not with `2`, which, for people unused to Prolog's little ways, tends to come as a bit of a surprise.

If we want to carry out the actual arithmetic involved, we have to explicitly force evaluation by making use of the very special inbuilt 'operator' `is/2`. This calls an inbuilt mechanism which carries out the arithmetic evaluation of its second argument, and then unifies the result with its first argument.

```
?- X is 1 + 1.  
X = 2  
yes
```

## Negation

There is no explicit negation in Prolog. Something is regarded as false if it cannot be proved. This is the so-called closed world assumption of Prolog.

Prolog does have an inbuilt mechanism for “negation as failure”. That is, we can ask it whether something cannot be proved by using the built-in prefix operator `\+`. The goal `?- \+ man(jules)` succeeds if and only if the goal `?- man(jules)` fails.

Variables in negated goals are not instantiated. Therefore, the following two goals are not fully equivalent.

```
?- likeFootMassage(Who)  
Who = mia  
yes  
  
?- \+ \+ likeFootMassage(Who)  
yes
```

## Backtracking and the Cut

When Prolog tries to prove a goal, the structure underlying it attempts can be regarded as a tree: a tree with branches that lead (or do not lead) to possible proofs. The Prolog inference engine essentially searches for a branch that makes the main goal true. Of course it may, and usually does, find itself in a branch that does not lead to a proof (that is, a branch that *fails*). Then Prolog automatically *backtracks* to the previous node in the tree and tries another (the next) branch. (If there is no previous node, this means that the goal is not provable, and Prolog tells us “no”.)

Backtracking can be forced by the user by entering a semicolon after Prolog gives a solution. This allows us to try generating more than one solution to a query. For example (reverting to our original knowledge base) we can demand that Prolog finds all the women as follows:

```
?- woman(Who).  
Who = mia;  
Who = jody;  
no
```

There are two ways to influence Prolog's search strategy: using the *cut* to suppress backtracking, or changing the order of the clauses in the database.

The *cut* (written `!`, it is a built-in Prolog predicate with arity 0) removes certain branches from the proof tree. If a cut is put in a clause, and Prolog encounters it during a proof, it removes all the clauses of the same predicate that are listed further down in the knowledge base, and moreover, removes all alternative solutions to conjuncts to the left of the cut in its clause.

The order of clauses play a role in Prolog's search strategy, since Prolog works on the database in a sequential way, and subgoals are proved from left to right in the search tree. (Sometimes the order even drastically determines the outcome of a proof.)

## Built-in Predicates

There is a set of built-in predicates available in Prolog. We briefly discuss the ones that we use in our programs. It should be noted though, that it depends on the Prolog version that you use, which predicates are built-in.

First we have the ones for controlling output. The predicate `write/1` displays a term to the current output device, and `nl/0` creates a new line.

Then there is whole family of predicates that are used for term manipulation. With these you can break complex terms into pieces or build new ones. The predicate `functor(T,F,A)` succeeds if `F` is the functor of term `T` with arity `A`. And `arg(N,T,A)` is true if `A` is the `N`th argument of `T`. In some case we prefer to make use of the so-called “univ” predicate, weirdly written as “`=..`”, that transforms a complex term into a list consisting of the functor followed by its arguments. For instance:

```
?- love(pumpkin,honey_bunny) =.. List.  
List = [love,pumpkin,honey_bunny]  
yes
```

For checking the types of terms: `nonvar(X)` is true if `X` is instantiated, `var(X)` is true if `X` is not instantiated. The predicate `simple/1` succeeds if its argument is either an atom or a variable, and `compound/1` if its argument is a complex term.

With `assert/1` and `retract/1` it is possible to change the knowledge base while executing a goal. The former asserts a clause to the database, the latter removes it. Many versions of Prolog require a `dynamic` declaration of those predicates that are modified by other predicates, as we do with the counter for the skolem index in the library file.

Finally, there is some predefined stuff that gives controll over backtracking. The very rude `fail/0` predicate causes Prolog to backtrack (this is used to generate more solutions). With

`bagof/3` it is possible to generate all solutions of a specific goal, and put the instantiations of a certain variable (or complex term with variables) in a list. E.g., the goal

```
?- bagof(Who,woman(Who),Answer).
Answer = [mia,jody].
yes
```

tries to satisfies the goal in the second argument of `bagof`, and for each solution it puts the value of its first argument (`Who`) in its third argument, the list `Answer`. The predicate `setof/3` functions similarly, but it removes duplicate answers.

## Difference Lists

A difference list `List1-List2` is a way of using two lists (namely, `List1` and `List2`) to represent one single list (namely, the *difference* of the two lists).

For example, the three element list `[pumpkin,butch,jimmy]` can be represented as the following difference list:

```
[pumpkin,butch,jimmy,lance]-[lance]
```

or as the following one:

```
[pumpkin,butch,jimmy]-[]
```

Indeed, there are infinitely many difference list representations of `[pumpkin,butch,jimmy]`. In all of them, the first list in the difference list representation consists of the list we are interested in (namely `[pumpkin,butch,jimmy]`) followed by some suffix, while the second list is that suffix. So a difference list is simply a pair of list structures, the second of which is a suffix from the other. We follow the usual convention of using the built-in operator `-` to group the two list together. (However, note that we don't have to do this: any other operator would do.)

Let's go a step further. Suppose we take the suffix to be a variable. Then any other difference-list encoding of `[pumpkin,butch,jimmy]` is an instance of the following *most general difference list*.

```
[pumpkin,butch,jimmy|X]-X
```

In practice, we will use the term *difference list* to mean the most general difference list. The empty list is represented by the difference list  $X-X$ .

Why on earth should anyone want to represent lists as difference lists? There is a simple answer: efficiency. In particular, when we use the difference list representation, Prolog can perform concatenation of lists much faster. For example, the usual `append/3` for normal lists is a recursively defined predicate that can be inefficient for large lists. (This is because Prolog must recursively work its way down the entire collection of first/rest pairs.) On the other hand, when we make use of difference lists `append/3` can be defined as follows.

```
append(X-Y,Y-Z,X-Z).
```

Consider how this works. Suppose we want to append `[pumpkin,butch]` to `[jody,lance]`. Then we make the following query:

```
?- append([pumpkin,butch|E]-E,[jody,lance|F]-F,A-B).
```

This causes `A` to unify with `[pumpkin,butch|E]`, `E` with `[jody,lance|F]`, and `B` with `F`. As a result, `A-B` unifies with `[pumpkin,butch,jody,lance|B]-B`, which is a difference list of the four items `pumpkin`, `butch`, `jody`, and `lance`.

The reader who works through this example will see that what makes difference list representations so efficient is that the suffix variable gives us direct access to the end of the list. In the conventional first/rest representation we have to work our way recursively down towards the end of the list. Difference list representations avoid this overhead. We have to pay a price for this gain in efficiency (difference list representation is less transparent) but in many circumstances this is a price worth paying.

## Definite Clause Grammars

Definite clause grammars (DCGs) are the in built Prolog mechanism for defining grammars. Actually, they are really a syntactically sugared way of working with certain difference lists. With DCGs you can kill two birds with one stone: if you define the grammar rules you'll get the parser for free!

Here is a DCG for a very small fragment of english grammar. We have defined syntactic categories `s`, `np`, `vp`, `det`, `noun`, and `tv`, standing for sentence, noun phrase, verb phrase, determiner, common noun, and transitive verb. These are also called the *non-terminal* symbols. Every rule in the DCG has a non-terminal symbol on its left hand side.

```
s --> np, vp.
```

```
np --> det, noun.  
np --> [mia].  
det --> [a].  
noun --> [man].  
noun --> [five,dollar,shake].  
vp --> tv, np.  
vp --> [drinks].  
tv --> [loves].
```

On the right hand side of the rules, you'll either find one or more non-terminal symbols, or a terminal symbol. The terminal symbols are the lexical entries, the actual words of the language of our interest.

Now, what do these rules mean? They are very intuitive indeed. The rule `s --> np, vp` says that a syntactic category called `s`, consists of an `np`, followed by a `vp`. Similarly, according to this DCG, the category `noun` is either the string `man`, or the sequence of strings `five dollar shake` (represented in lists). And so on.

This DCG covers sentences like `Mia loves a five dollar shake`, `A man drinks`, but not: `A woman loves` or `Mia drinks a one dollar shake`.

To parse sentences, we can pose a query like:

```
?- s([mia,loves,a,five,dollar,shake], []).
```

This goal is satisfied if the sequence of words in the first argument belongs to `s`. There is only one rule for `s` in our DCG. It says that an `s` can be replaced by an `np` followed by a `vp`. That is, we have to take some items of the input list that form a noun phrase, in such a way that the rest of the items on the list form a verb phrase. Since there is the rule

```
np --> [mia].
```

in the knowledge base we now have to proof whether

```
?- vp([loves,a,five,dollar,shake], []).
```

which is provable indeed (we leave this is an exercise to the reader). And this is basically how parsing with DCGs takes place on the surface level. However, Prolog doesn't use our DCG rules directly for the purpose of parsing. The DCG is translated internally into the following clauses:

```

s(A,B) :- np(A,C), vp(C,B).
np(A,B) :- det(A,C), noun(C,B).
np([mia|B],B).
det([a|B],B).
noun([man|B],B).
noun([five,dollar,shake|B],B).
vp(A,B) :- tv(A,C), np(C,B).
vp([drinks|B],B).
tv([loves|B],B).

```

The alert reader will notice that these clauses look surprisingly familiar. In fact, they are the direct encodings of difference lists (in the facts, for example `noun([man|B],B)`) and the appending of two difference lists (in the rules, for instance

```

s(A,B) :- np(A,C), vp(C,B).

```

can be read as: `s` is a difference list `A-B` if we can prove that is the result of appending difference list `A-C` to `C-B`).

Since, as we just noticed, DCG rules are normal Prolog clauses, it is perfectly allowed to add arguments to the rules. Some useful stuff we can add to our grammar is information on agreement. Suppose we want to include noun phrases like *all boxers* in our grammar by adding entries for *all* and *boxers*:

```

det --> [all].
noun --> [boxers].

```

Be careful though! Adding these clauses make it possible to parse *Mia loves all boxers*, but also non-grammatical *All man drinks* or *A boxers loves all woman*. Clearly, our grammar lacks information about agreement. However, this information can be added very easily to the rules. Let's do it for the determiners and nouns first (and why not add some extra entries at the same time):

```

det(plural) --> [all].
det(singular) --> [a].
noun(singular) --> [boxer].
noun(plural) --> [boxers].
noun(singular) --> [man].
noun(plural) --> [men].
noun(singular) --> [five,dollar,shake].
noun(plural) --> [five,dollar,shakes].

```

Since `det` and `noun` have an extra argument now, all the rules that have these symbols at their right hand side (this is the `np --> det, noun.` rule in our current grammar) should get an extra argument as well. As can be seen from the entries above, the value of this argument is either `singular` or `plural`. Since we want the determiner to have the same agreement as the noun when they are combined to a noun phrase, we could write the following code:

```
np --> det(singular), noun(singular).
np --> det(plural), noun(plural).
```

But there is much more elegant way of encoding this. We can bring in a variable that, during parsing, gets instantiated with the agreement value of the determiner and noun, and collapse the above rules into one:

```
np --> det(Agr), noun(Agr).
```

Nevertheless, from the examples given earlier, we also want to add agreement features to noun phrases and verb phrases. We won't do explain this step by step — the principle should be clear now — but list the entire rewritten grammar including agreement, and extended with some new entries, below.

```
s --> np(Agr), vp(Agr).
np(Agr) --> det(Agr), noun(Agr).
np(singular) --> [mia].
det(plural) --> [all].
det(singular) --> [a].
noun(singular) --> [boxer].
noun(plural) --> [boxers].
noun(singular) --> [man].
noun(plural) --> [men].
noun(singular) --> [five,dollar,shake].
noun(plural) --> [five,dollar,shakes].
vp(Agr) --> tv(Agr), np(_).
vp(singular) --> [drinks].
vp(plural) --> [drink].
tv(singular) --> [loves].
tv(plural) --> [love].
```

Now look at our grammar. From an aesthetic point of view, there certainly is some space for improvement! Everything is mixed up: the rules and the lexical entries together form

one chaotic DCG. Consider what these grammar would look like if we extend its coverage to a more serious fragment of english!

One way to bring in some organisation in the grammar, is to make a physical distinction between the lexicon and the grammar rules. The lexicon might be designed as follows:

```
lexicon(np,singular,mia).
lexicon(det,plural,all).
lexicon(det,singular,a).
lexicon(noun,singular,boxer).
lexicon(noun,plural,boxers).
lexicon(noun,singular,man).
lexicon(noun,plural,men).
lexicon(vp,singular,drinks).
lexicon(vp,plural,drink).
lexicon(tv,singular,loves).
lexicon(tv,plural,love).
```

That is, normal Prolog facts of the form `lexicon/3`, with the first argument stating the syntactic category, the second argument the agreement value, and the third the word itself. The only thing left to do is to make a connection between this lexicon and the grammar rules. DCGs have a neat way to do this, normal Prolog goals can be included in the rules included in curly brackets. This is the result:

```
s --> np(Agr), vp(Agr).
np(Agr) --> [X], {lexicon(np,Agr,X)}.
np(Agr) --> det(Agr), noun(Agr).
det(Agr) --> [X], {lexicon(det,Agr,X)}.
vp(Agr) --> tv(Agr), np(_).
vp(Agr) --> [X], {lexicon(vp,Agr,X)}.
tv(Agr) --> [X], {lexicon(tv,Agr,X)}.
```

## Notes

In this appendix we summarized the basic concepts of Prolog. We hope it will be a handy reference, however it is *not* intended as a substitute for good introduction to Prolog. The reader who wants to learn about computational semantics, but who knows no Prolog, is strongly advised to put this book aside for a while and study one of the many excellent Prolog texts currently available. We particularly recommend the following ones. For a succinct, no-frills overview, try Clocksin and Mellish (Clocksin and Mellish 1987). For a leisurely, in-depth introduction to programming in Prolog, try Bratko (Bratko 1990). For

a more theoretically oriented introduction, try Sterling and Shapiro (Sterling and Shapiro 1986). Finally, for an introduction specially geared towards computational linguistics, try Pereira and Shieber (Pereira and Shieber 1987).

# Appendix E

## Listing of Programs

This appendix includes the full program listings that are developed in this book. Most predicates are decorated with a short documentation, using the following notational conventions for its required argument instantiations:

`:Arg` Argument `Arg` should be instantiated to a term denoting a goal

`+Arg` Argument `Arg` should be instantiated

`-Arg` Argument `Arg` should not be instantiated

`?Arg` Argument `Arg` may or may not be instantiated

Since Prolog's birth in the beginning of the seventies, a number of Prolog dialects emerged, and not all agree on a syntax or the in-built predicates. The programs in this book follow the conventions of "Standard Prolog", the ISO international standard on Prolog (Deransart, Ed-Dbali, and Cervoni 1996), as close as possible. The following predicates are assumed to be built-in in your version of Prolog (such as for example Quintus or Sicstus Prolog):

### All solutions

`bagof/3`

`findall/3`

### Arithmetic comparison

`>` (arithmetic greater than)

< (arithmetic less than)

## Arithmetic evaluation

is/2 (evaluate expression)

## Atomic term processing

atom\_chars/2 (conversion of atoms to character codes and vice versa)

## Character input

get0/1

## Clause creation and destruction

asserta/1 (clause creation)

retract/1 (clause destruction)

## File consultation

[File|Files ] (consult list of files)

## List operation

length/2 ] (determine length of a list)

## Logic and control

,/2 (conjunction)

;/2 (disjunction)

!/0 (cut)

fail/0

true/0

\+ (not provable)

## Operator definition

op/3 (extending operator table)

## Term comparison

==/2 (term identical)

## Term creation and decomposition

arg/3

functor/3

=../2 (the “univ”)

## Term unification

= (unify)

## Type testing

atom/1

atomic/1

compound/1

nonvar/1

var/1

## Term output

write/1

nl/0

The following is a practical overview of the programs in this appendix. We start with the library files consulted by most of the other programs, and then give a chapter by chapter break-down description of the files.

/*=====

    Read Predicates
    -----

readLine(-WordList)
    Outputs a prompt, reads a sequence of characters from the standard
    input and converts this to WordList, a list of strings. Punctuation
    is stripped.

readWords(-WordList)
    Reads in a sequence of characters, until a return is registered,
    and converts this to WordList a list of strings.

readWord(+Char,-Chars,?State)
    Read a word coded as Chars (a list of ascii values), starting
    with with ascii value Char, and determine the State of input
    ('ended' = end of line, 'notended' = not end of line).
    Blanks and full stops split words, a return ends a line.

checkWords(+OldWordList,-NewWordList)
    Check if all words are unquoted atoms, if not convert them
    into atoms.

convertWord(+OldWord,-NewWord)
    OldWord and NewWord are words represented as lists of ascii values.
    Converts upper into lower case characters, and eliminates
    non-alphabetic characters.

    version: November 12, 1997; March 9, 1999.
    description: Lexical entries for a small coverage of English
    authors: Patrick Blackburn & Johan Bos

```

This file contains the lexical entries for a small fragment of English. Entries have the form `lexicon(Cat,Sym,Phrase,Misc)`, where Cat is the syntactic category, Sym the predicate symbol introduced by the phrase, Phrase a list of the words that form the phrase, and Misc miscellaneous information depending on the the type of entry.
